This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

DIETETIC TREATMENT OF CHRONIC BRIGHT'S DISEASE.[1]

BY BEVERLEY ROBINSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE proper dietetic treatment of chronic Bright's disease of the kidney is a subject of certainly as much practical importance as its medicinal management, or the rules pertaining to clothing and climate. It is, therefore, a somewhat remarkable fact that but little, relatively, has been written in regard to it, at least of an accurate kind. Especially is this statement true for the past few years, when so many treatises, articles, and discussions have taken hold of the disease in question, from many different aspects. The pure pathologist has, by means of the microscope, unravelled much that was previously obscure; the physiologist has dealt extensively with the sphygmograph and the effects of increased blood-pressure; and the clinician has discussed fully matters of heredity, etiology, and symptoms, and facts pertaining to urinary analysis, in which he has also been aided by the chemist. Remedial treatment, indeed, has been much studied, but particularly with reference to drugs, to venesection, to clothing, and to climate changes. Meanwhile the subject of dietetic treatment has only been touched upon, as it were, by many writers. In looking through quite a number of general and special treatises, in which chronic Bright's disease is exhaustively described in many other particulars, I have found comparatively little on the subject of diet. Even this little is usually diffuse, or scattered, and is presented to the reader in a somewhat casual manner. General statements are made, but few definite rules are laid down, and the student, after considerable labor and effort, is left somewhat in doubt as to the best regimen to adopt in treating chronic Bright's disease under different circumstances. To the above rather sweeping statement I must in fairness make a few notable exceptions, since in Dickinson's work on "Albuminuria," in Tyson's "Treatise on Bright's Disease," in George Johnson's "Lectures on Bright's Disease," in Bartel's work, which forms the fifteenth volume of "Ziemssen's Cyclopædia," in T. Grainger Stewart's "Lectures on Albuminuria," in Ebstein's, Granville's, and in Roose's recent treatises on gout and its treatment, there is much about suitable regimen that is of the highest value and greatest clinical and scientific accuracy.

During the past few years, however, in only one or two of the journals to which I have access, do I find more than very short remarks upon the dietary treatment of chronic Bright's disease. To this statement I again make a partial exception, inasmuch as an article will be found entitled, "On Diet in Albuminuria," in the *Boston Medical and Surgical Journal*, December 2, 1886, pp. 513–515, but even this article is translated from advance-sheets of a lecture by Dujardin-Beaumetz, of Paris. In this lecture references are made to the works of Semmola, to Senator, Bouchardat, Jaccoud, etc., and especially to a thesis (1885) of Nollet, "A Study on the Alimentary Regimen of the Albuminuric." Doubtless if my researches had been more extensive I would have found important data on this subject; but they would probably have been somewhat ancient and of slight value at the present time.

In Bartholow's "Materia Medica and Therapeutics," the latest edition, attention is directed to the great benefit derived from the milk-cure, the skim-milk cure, and the buttermilk cure, but without specifying any reasons for their advantages. Alcohol is also briefly spoken of somewhat as diet is by many writers, although the consensus of opinion certainly is that it is usually injurious in chronic Bright's disease. Some authors go so far as to affirm that it should never be employed. Others, more rationally, admit its utility, but in a guarded manner, and only when special indications exist, such as exhaustion, brain anæmia, cardiac weakness, etc. While a strict milk diet is generally praised, it is recognized, in some instances that patients soon tire of it, or it becomes so repugnant to them that they cannot take it in sufficient quantity; and to preserve their strength we are compelled to vary their alimentation. This addition to their food may be in the form of broths, eggs, farinaceous substances. fish, or meat. If admitted at all to the diet list, the amount of these aliments has been variously estimated. In allowing meat once a day, for example, it is claimed that if the amount of albumin excreted by the kidneys be large, it was obtained originally from the blood, thus notably impoverishing it, and it is wise to make good the deficit by a proper amount of azotized food. Without advancing any similar argument, I will add that some writers, like Granville, advocate an abundant, varied, and very nutritious diet—indeed, as much food "as the appetite demands or the palate desires."

We thus appreciate how uncertain our opinions must be as regards the subject of dietetic treatment of chronic Bright's disease, unless we make a careful study of it, and endeavor to lay down more accurate rules for our guidance. It is toward accomplishing this object, in part at least, that this contribution to the discussion this evening is made. The indications for proper dietetic treatment in chronic Bright's disease vary somewhat, of course, with the form and stage of the renal degeneration, as well as with the nature of the secondary complications which may be present. In each case presented to us, it seems of practical importance to discover, if possible, the probable cause of the actual disease, and the dietetic treatment should be directed more or less in accordance with the discovery made. Thus, if excessive eating or drinking be the obvious exciting cause, considerable limitations as to food and drink seem rational and well ordered. If gout be manifestly present, in an hereditary or acquired form, there are certain aliments and beverages that should be specially prohibited. I shall now proceed to consider, as well as I can, the dietetic treatment of chronic Bright's disease in three forms of renal degeneration which have been widely recognized.

I. Chronic parenchymatous nephritis (the large kidney without waxy degeneration).

II. Lardaceous disease of the kidney (waxy kidney).

III. Interstitial nephritis (the small granular kidney).

I. The first form may begin, as already stated, insidiously, as a chronic disease, or it may be a direct sequel of acute nephritis. The exact time when the kidney which has been affected with acute inflammation becomes a large white or mottled kidney, can scarcely be determined clinically in a very precise manner. Fortunate it is, therefore, that rules of diet which may be properly ap-

[1] Read at a meeting of the Practitioners' Society, November 16, 1888.

plied to this intermediate stage are equally good for the treatment of any chronic changes.

All dietary rules pertain to: 1. Food. 2. Drink. 3. Stimulants.

1. *Food.*—The best diet in chronic parenchymatous nephritis is generally recognized to be an exclusive milk diet. The reasons given for this preference and which appear to me important, may be enumerated as follows: (1) Milk is easily assimilated, and is therefore well adapted to a disease in which digestive disturbances are almost the invariable rule. These disturbances are, generally, as we know, of the nature of dyspepsia, nausea, vomiting, epigastric pains, etc. (2) If a suitable amount of milk be taken daily, it provides sufficient nutriment for the needs and proper support of the economy. (3) An exclusive milk diet forms less urea in the blood than any other form of alimentation. (4) Milk furnishes a large quantity of fluid to flush out the kidneys with, always supposing it is taken at short intervals and in fairly large quantities each time. In this way it increases urinary excretion by continued excessive pressure in the arterial system, and thus helps the dropsy to disappear by degrees.

The objections which are, or may be urged against an exclusive milk diet are: First, it is not tolerated by all patients. Some persons soon tire of it, or get a profound, unconquerable disgust for it. There are a few individuals, also, in whom, I am convinced, an idiosyncrasy has much to do with this distaste, and try as we may to get them to take milk in any useful quantity, we are finally obliged to abandon the effort in sheer despair of success. In either of these two contingencies, we are obliged to recur to the use of broths (chicken and veal), beef-tea, light farinaceous food, and other diluents than milk.

2. *Drinks.*—Of these the best is unquestionably pure water, preferably distilled, according to Dickinson, and of this about two or three pints daily may be advisable. Soda-water, or cream of tartar lemonade may also be permitted, if either stomachal intolerance or constipation be unpleasant symptoms in the case.

Another beverage used and recommended in Bright's disease by Professor Semmola, of Naples, is formulated as follows:

℞. Sodii iodidi..... gr. xv.
Sodii phosphat..... gr. xxx.
Sodii chlorid..... ʒ jss.
Aqua fontana..... Oj.

This may be drunk daily, pure, or mixed with milk if the taste is objectionable. Good effects are claimed from its use.[1] Personally, I doubt the utility of distilled water, as I believe its lack of aeration is a drawback to its potability and digestibility. Mere shaking it in contact with atmospheric air will not supply what is needed, and I object somewhat to artificially aerated waters made under pressure, as, I believe, they are apt, when taken in large quantities continuously, to distend the stomach and bowels with carbonic acid gas, and increase after a time the discomfort of the patient. I would recommend, after several satisfactory trials and on account of its great purity, limpidity, and perfect ease of digestion, pure spring water as being a very desirable beverage. The first great thing to accomplish is, at all events, to have these patients drink much pure water, up to several pints a day, and yet not upset an already weak digestion in doing it. The use of water abundantly as a diuretic in renal disease does not antagonize the principle of giving the kidney little or moderate work to do, as it is a physiological diluent, and does not occasion any irritation of the kidneys. Some other diuretics, among which we may at times place digitalis, are prone to induce this untoward effect, either directly or by increasing heart-action, and contracting the small renal arteries. This is not true, however, of mild alkaline water, soda-water, or cream of tartar solution with lemon in it (Imperial drink). By these different means a marked flow of urine is obtained and the kidneys are kept continuously flushed, so that the masses of degenerated epithelium which tend to clog the tubes are gotten rid of. In this manner any remaining congestion of the gland will be relieved by secretion, and the system will be cleared of impurities which previously had been retained. By the passage of a large quantity of fluid through the kidneys we also reduce to a minimum (dilute?) that nitrogenous excess which finds its way out through these organs, and gives rise to many sources of irritation. If at the same time we cut off the materials of urea and uric acid, we are doing the best we can accomplish (Dickinson).

Tolerance of milk, however, when pure milk is objected to, may often be obtained, if we mix it in certain variable proportions with lime-water, carbonic water, Vichy, etc., or give it in the form of peptonized milk or koumyss.[1] Whenever milk is well supported by the stomach it may be taken either skimmed or unskimmed, that is to say, with or without the cream. Unskimmed milk is advantageous, says George Johnson, because it prevents constipation. It is desirable, according to Tyson, because its nitrogenous principle, the casein, is present in a proportionately small amount as compared with skimmed milk. On the other hand, the stomach is often intolerant to rich milk, and the fatty elements in the cream are apt to occasion numerous dyspeptic symptoms, such as headache, heartburn, diarrhœa, etc. Under these circumstances the milk had better be skimmed rather than abandon it as the main article of diet. Even though we are obliged to do this, or to adopt many different methods to make milk tolerable to irritable stomachs, we should try all means which offer any chances of success before abandoning it altogether. Sufferers from chronic Bright's disease are so frequently affected with gastric symptoms which may prove both obstinate and distressing, that it will scarcely do to give up milk diet without a prolonged struggle to avoid it if possible. The probabilities are that many dyspeptic symptoms are occasioned by vicarious elimination, through the mucous membrane of the stomach, of impurities which normally are excreted by the kidneys. This is proven by the fact that the gastric secretions are at times mingled with the products of decomposed urea. Of course, when this is the case, relief should be sought, partly at least, in suitable diet, and iced milk in small quantity can occasionally alone be taken. If this fail us, nutritive enemata must be resorted to in order to sustain the patient until incessant vomiting be stopped. When taken, milk may be either warm or cold, as best suits the patient. It is usually found that if great irritability of the stomach be present, it is more acceptable cold, in small quantities and at short intervals. If it form the exclusive diet, it must be taken in fixed quantities and at specified hours. From a few ounces to half a pint, or one pint, may be taken every two or three hours by an adult. From two and a half to four quarts in the twenty-four hours are sufficient to prevent bodily loss and to keep its condition about stationary.

In children affected with chronic Bright's disease milk diet acts extremely well, and while they are upon it there is no need for them to have any other food or drink. Of course they will take less milk than adults in proportion to their ages. Clinically there is evidence to show that exclusive milk diet (or nearly so) reduces notably the quantity of albumin excreted by the kidneys. In order to prove this, if possible, to my entire satisfaction, I endeavored to obtain some careful observations in my medical service at St. Luke's Hospital, about two years ago. For the work done at that time I am indebted to Dr. E. B. Dench, who was then senior assistant in my wards. The report prepared at the date referred to, by Dr. Dench, was based on the medical records of St. Luke's, and was referred to by me, in a debate which took place on the subject of this paper, before the Academy of Medicine, at a Stated Meeting held March 16, 1886. A brief ac-

[1] Bull. Gén. de Thérapeutique, November 30, 1886. Boston Medical and Surgical Journal, loc. cit.

[1] I do not believe the small quantity of alcohol in the latter is ever injurious, and it is sometimes retained upon the most irritable stomach.

count of the discussion was published in THE MEDICAL RECORD, March 27, 1886, p. 372. From the printed text there found I take the following:

"During the last two years 70 cases of chronic Bright's disease have been treated—uncomplicated, 26; complicated, 44. In the great majority of the cases the diet was milk and farinaceous food. In several cases the addition of the farinaceous or nitrogenous food caused a diminution of the urinary secretion for twenty-four hours. In some cases such an addition increased the quantity of albumin in the urine. In one case the quantity of urine was increased by the addition of farinaceous food. The duration of treatment, dietary and medicinal, was from one to three months.

"To test roughly the effect of different kinds of dietary treatment on the amount of albumin excreted, Dr. Dench made experiments in three cases. The estimations of the albumin were volumetric, the Doremus test for urea was used. In Case I. the milk diet diminished the amount of albumin, and the addition of farinaceous and light diet (small quantity of meat) caused an increase in the amount of albumin. In Case II. there seemed to be no relation between the diet and the quantity of albumin in the urine. In Case III. albumin was increased after the addition of meat to the diet, except in one instance, the observations being made for several days."

In the cases reported by Dr. Dench, with the exception of the three experimental cases, as you will remark, medicinal measures were employed concomitantly with dietetic treatment, and it cannot therefore be accurately known from his summary of cases what results are due to drugs and how much to mere diet. The only manner, of course, in which reliable data of a desirable kind, in reference to this point, can possibly be obtained, would be by a series of carefully noted observations, based on cases treated solely by diet, and others in which medicinal agents were also employed. As a matter of corroborative experiment, and as an addition to our acquired knowledge, although there are but three cases in my experience, I would emphasize the statements made by Dr. Dench, in regard to the effect of diet without medicines as compared with those instances in which diet plus medicines have been employed, upon the excretion of albumin by the kidneys. Careful notes were also taken in one of our cases as to the amount of urea excreted while the patient was on different kinds of dietary regimen. From personal remembrance, and from a note received from Dr. Dench on November 12, 1888, it would appear that "the amount of urea was somewhat increased while the patient was on milk diet. . . . The experiments were not carried very far, as they did not seem to show much." The query may be made in some cases as to whether the increased amount of urea in the urine, when the patient is on milk diet, is evidence of the beneficial effect of the diet or not. Only continued and careful observations can always, in my opinion, solve this problem satisfactorily. It is certain that the small quantity of urea excreted by the kidneys often alarms us, since we feel confident that it must be retained in the blood, and to its great injury. Now, any dietary management which in these cases increases the amount of urea excreted, would appear to be beneficial; yet, on the other hand, those who see in a nitrogenous diet a faulty management of chronic Bright's disease, are led in part to this conviction by the observed increase of urea in the urine, which is so frequently found when such a dietary has been followed, and by their recognition that this fact clearly means increased work on the part of the diseased organ in question, viz., the kidney.

The prognosis, however, of chronic Bright's disease depends "not on the hyper-albuminosis, but on the more or less profound alterations of the kidneys, and the retention therefrom resulting of extractive matters, and of those toxic products which Bouchard has made known to us under the name of urotoxine. Uræmia, the terminal period of albuminuria, depends, then, not on the quantity of albumin contained in the urine, but on the state of the renal filter."[1] If this be admitted, is it not better for the economy to get rid of the poisonous products rather than to keep fast hold of them? and is not the renal filter presumably in better working order when it can perform its functions in a moderate rather than in a minimum degree?

The problem is obviously most difficult and many-sided. Suffice it for me to have at least indicated certain directions which discussion may profitably take.

The best results obtained by Tyson from an exclusive milk diet were when the patient remained in bed, and was thus completely at rest. This is not at all surprising, since we are all familiar with the supposed effect of bodily fatigue in augmenting albuminuria. Experimentally, Sparks and Bruce ("Med.-Chir. Trans.," vol. lxii., p. 254) have also shown the effect of an absolute milk diet in diminishing the amount of albumin excreted. This reduction likewise took place in a notable degree when an absolutely non-nitrogenous diet alone was allowed. The reduction obtained with absolute milk diet, in the case reported by them (of a patient suffering from chronic phthisis) was from a mean of $\frac{1}{6}$ to $\frac{1}{8}$ albumin in the urine; with ordinary diet (viz., a moderate amount of meat, with vegetables, abundance of milk and farinaceous food, no stimulants), from $\frac{1}{16}$ to $\frac{1}{30}$ on the first day of experiment, and from $\frac{1}{30}$ to $\frac{1}{40}$ on the second day of experiment. In this case, on the second day, the patient complained of a sensation of unsatisfied hunger and of sinking, and declared that he could not continue an absolute milk diet very long. The amount of milk given was probably too small, being four and a half pints.

The conclusions to be drawn are much in favor of milk diet. Considering that few patients in moderate health can tolerate a purely fluid diet for any length of time, the result of experiments suggests that the diet in albuminuria should consist of milk, at any rate as far as can be borne (Sparks and Bruce). In subsequent experiments ordinary diet plus water was tried against ordinary diet plus milk. The result was not in favor of addition of milk to ordinary diet, but rather the opposite, and would appear to indicate that to produce a diminution of albumin in Bright's disease milk must be given not to supplement, but to replace, to a certain extent, the articles of ordinary diet.

Experiments with non-nitrogenous diet, viz., mashed potatoes, water, arrowroot, rice, fat bacon, butter, fried cabbage, showed a reduction in the amount of albumin excreted. The effect of withdrawal of nitrogenous food on the excretion of albumin does not cease with restoration of nitrogen to diet, but persists for a certain period afterward. This is explicable on the assumption that albumin which passes out of the blood into the urine is in part residue of a *luxus consumptus* of nitrogenous food. Hence, when nitrogen is restored, the organism makes good its losses, and albumin does not reappear in urine until this process is completed.

Second conclusion: The effect of milk diet is not merely apparent and due to albumin being more than ordinarily diluted, for ordinary diet with an equal quantity of water did not produce the same result.

In this connection I desire to direct attention to some observations being made at the present time at St. Luke's Hospital, in my wards, upon a patient who is suffering from chronic Bright's disease. The history, and detailed observations on the urine are entirely the work of my junior assistant, Dr. W. H. Caswell, to whose courtesy and knowledge I am glad to express my indebtedness. The history reads as follows:

F. G——, admitted July 6, 1888, aged twenty-seven; single; English; waiter. Family history negative. Patient had rheumatism four and a half years ago, has never had scarlet or intermittent fevers; denies specific disease; had gonorrhœa two years ago; has used alcohol freely; no history of pulmonary or cardiac disease. For several years has been troubled with indigestion; no vomiting. Twelve

[1] Beaumetz, loc. cit.

days before admission, on getting up in the morning, he noticed swelling around his eyes. He went to work as usual; at night he noticed that his penis was swollen. The next day his feet and legs were swollen, and he had a dull pain and stiffness across his back. Has had some headache. He passes urine frequently, but a small quantity at a time; more now than at commencement of the attack; he has been in bed for five days.

On admission is well nourished; anæmic; bowels regular; appetite fair; tongue slightly coated; pulse, 66; respiration, 24; temperature, 99.2° F.; urine, 1.018, alkaline, forty per cent. albumin (roughly estimated by volume); no glucose, granular, nucleated, and fatty casts.

July 10th.—Urine, granular casts and red blood-cells. Physical examination: Heart, apex-beat diffused, by auscultation in fifth space outside nipple line; action slow; faint systolic murmur over pulmonary area. Lungs, liver, spleen, abdomen, negative; inguinal glands enlarged on right side; prepuce swollen; some œdema of legs; considerable œdema of feet.

Urine Record, with Esbach's Apparatus.

In analyzing this history carefully we note the following facts: Patient put on a milk diet with distilled water q.s. to drink, rest in bed, infusion digitalis, liq. ammon. acet., and tr. ferri chlor. from July 8th to July 25th. At last date bulk of urine nearly the same as on July 8th, but amount of albumin excreted about forty per cent. less. Query: Was it effect of diet, of medicine, of rest, or all combined? During twenty days of the same treatment, from July 10th to July 30th, the specific gravity of the urine had became lower. Does this show advance of renal changes despite the fact that amount of albumin excreted on days mentioned was about the same?

On August 8th, patient had been sitting up during three days, and the amount of albumin excreted was more than doubled. On August 15th, patient still sitting up, and yet amount of albumin again notably diminished. On September 3d, light diet allowed without meat. On September 12th and 19th, amount of albumin estimated, and found to be notably increased. It was again estimated on September 30th, and found very much increased. From September 3d to September 30th, patient had same medicinal treatment as on August 29th, and from that date to September 3d. Yet on August 29th the quantity of albumin excreted was much smaller than on September 12th, 19th, and 30th. Inference to be made is clearly that light diet had increased amount of albumin excreted in twenty-four hours. It should be noted that patient had been permitted to walk about, but he was also walking about on August 29th, when quantity of albumin excreted was small.

On October 13th, 18th, and 24th, same light diet, but on each occasion amount of albumin was found to have diminished, and that too, progressively. The medication, however, had been changed from digitalis to caffein.

* From September 19th, specific gravity under normal.

† From October 29th to November 9th, amount of urine greatly increased, but albumin also. Query: Is amount of increase in bulk caused by caffein, or by caffein and mag. sulph.?

On November 1st, same light diet (everything like bread, vegetables, eggs, etc., without meat) and caffein, yet albumin excreted had increased in amount. I believe it will be admitted that this case is somewhat unsatisfactory in regard to any absolute diet-theory, because, while at one time light diet seemed undoubtedly to cause increase of quantity of albumin excreted, at another time the albuminuria with the same diet decreased progressively. It is true the medication was changed, and hence we remain in doubt as to the effect of the diet alone on the amount of albuminuria. The third conclusion of Sparks and Bruce is to the effect that "eggs in excess did not reduce the quantity of albumin in the urine." Nor should we expect that they would? On the contrary, we should expect that eggs would notably increase the amount of albumin in the urine. The experiments of Legart, Brown-Séquard, Hammond, Stokvis, and Claude Bernard, prove this. "Of things prohibited," Dujardin Beaumetz[1] "places eggs first in the category."

Uncooked eggs are worse, but "it is better to be chary in the employment of eggs, even when cooked, in albuminuria." On the other hand, Löwenmeyer[2] concludes, as a result of his experiments, with the addition of six to nine eggs a day to the dietary, "that an alimentation even very rich in albuminoid matters causes no increase in the amount of albumin in the urine."

After a time an exclusive fluid diet may do harm to the patient by occasioning a superabundant secretion of urine, and in this way, also, too great elimination of albumin from the system. It is also found that, in those individuals whose stomachs have already become very sensitive, great dilution of the gastric juice will give rise to dyspeptic symptoms.

When, in addition to these, or, indeed, independently of them, symptoms of general anæmia, exhaustion, etc., become manifest, and especially if the quantity of albumin in the urine be small, the exclusive milk-diet should be supplemented by a due proportion of farinaceous or vegetable food. Finally, even this diet may become objectionable, as it obliges the stomach and intestines to perform more work than they can properly accomplish, and whenever this condition is tolerably evident a moderate amount of broiled or roast meat should be allowed daily. The time at which meat is taken is not an indifferent matter, and, in my judgment, it should form part of an early dinner, which may include a slice of bread with a little butter. The rule here laid down is a good one to be followed, even by gouty patients, and despite the fact that meat is recognized by nearly all observers, in its quality of a most highly azotized substance, as increasing the quantity of urea and analogous compounds in the blood, which the kidneys in their disabled condition are unable entirely to excrete. While meat, therefore, under the circumstances mentioned, may be allowed in moderate quantities, more than this would unquestionably aggravate the situation. Although this is true, we would not have the same reason to fear uræmic symptoms in this form of kidney disease as in interstitial nephritis or so-called gouty kidney. According to Fagge,[3] the generally received opinion in regard to this matter is erroneous. He writes as follows: "The statement commonly made, that this form of kidney disease (cirrhosis of the kidney) is the one above all others in which uræmia is apt to occur, appears to be traceable to the fact that the advanced stages of parenchymatous nephritis have been so generally mixed up with it."

In those cases in which the disease is progressing satisfactorily dropsy disappears, while albumin is still present in the urine. It is important for the patient at this period to avoid any errors of diet until the urine has regained its normal character.

Stimulants.—As a rule, all stimulants are injurious in the dietetic treatment of chronic parenchymatous nephritis. In any form alcohol increases the work of the kidneys, augments the quantity of urea in the blood, and promotes increased excretion of albumin. Claret and the light French and German wines are perhaps the least objectionable. Gin, or whiskey much diluted, are occasionally of value as diuretics. It may be stated as a cardinal law that the non-inebriant drinks alone are those which have no harmful effects, or are, as a rule, of any special utility. Even a small quantity of certain wines, like Moselle, Madeira, or Champagne, will increase immediately and considerably the quantity of albumin excreted. According to Sparks and Bruce, the most injurious of all stimulants in this respect is Madeira. In regard to the question of using alcohol, it should be continually borne in mind that its consumption, by the extra work it imposes on the kidneys, is opposed to the principle of lessening as much as possible the labor of the altered gland-tissue. It should also be remembered, particularly among the lower classes, that excess in taking alcohol has been believed by many distinguished observers to be one of the most frequent causes of albuminuria. If this view be only at times correct, it may be inferred in certain cases that a moderate employment of alcohol may tend to "perpetuate and aggravate" the disease when it is obviously due to other causes. It is further proven by clinical experience that alcoholic stimulants produce greater and more pernicious effects when there are considerable renal changes than would result from an equal quantity given when the kidneys are in a normal condition. Despite all these objections, conditions may arise when alcoholic stimulants are imperatively called for. Such instances are those which occur whenever great exhaustion is present, as by reason of blood-losses from albuminuria; and in instances in which there is profound anæmia, particularly of the brain. This condition is often, as we know, the accompaniment of threatened uræmic symptoms, viz., convulsions, dyspnœa, etc., when the economy is literally poisoned by retained urinary excreta. Under these circumstances alcoholic stimulants are needed, and may be given as freely as the occasion seems to require. In some instances, no doubt, the uræmic attack may be aborted, owing to the fact that more blood is sent to the brain, which is deprived of it, and the heart, which is beating rapidly and feebly, is strengthened and great temporary relief is thus afforded. In these cases we should scarcely look for much help from malt liquors or wines, but must place our reliance upon the strongest alcoholic liquors, viz., brandy or whiskey.

II. The dietetic treatment of lardaceous disease of the kidney depends somewhat upon its cause, if it continues to be present. If it be phthisis, abundant and nourishing food should be given, of which milk and cream should form a large portion, but meat should not in these cases be denied, while alcohol should be allowed in moderate quantities, and good wine is often a great boon to the sufferer. In this manner the loss the general system suffers from profuse suppuration is in some degree compensated. From a theoretical stand-point, a good beef-extract is useful, as an addition to daily diet, by reason of the saline constituents of beef which it supplies in a concentrated form. When the disease has disappeared which has been the cause of the renal changes, the dietetic regimen should not differ materially from that which I have counselled for parenchymatous nephritis.

III. The dietetic treatment of interstitial nephritis should have mainly in view: 1. To maintain the integrity of the blood by preventing the accumulation of urea and allied compounds. 2. To compensate the loss by albuminuria.

As regards the food, we should be particularly careful in its choice, for the reason that the patient's appetite is often good, and nutrition may be kept up without causing unnecessary risks. It is all-important to bear in mind that the urea which accumulates in the blood is largely formed from nitrogeneous food, and is increased in pro-

[1] Loc. cit.
[2] THE MEDICAL RECORD, December 11, 1886, p. 657. Lyon Médical, No. 38, 1886.
[3] Practice of Medicine, vol. ii., pp. 494, 495.

portion to the amount of this kind of food taken. Of course, the more urea accumulated the more the kidneys are called upon to work to eliminate the excess through their excretion. It is neither possible nor desirable to prohibit all nitrogeneous food, yet it is evident the amount allowed should be very moderate. In place, therefore, of considerable meat-diet, milk and cream should be supplied abundantly, and the other necessary elements of food should be obtained from the vegetable kingdom. While it is admitted that a diet thus formulated may not give the greatest physical strength, it will at least maintain the nutrition in fairly good condition. It is also widely accepted that patients thus treated may apparently enjoy tolerable health during many years. In the latest contribution on this subject from a distinguished investigator and writer,[1] I find the following: "The degree of restriction, speaking of proteid substances, should be determined by the seriousness of the symptoms. Their use should at least always be moderate. In advanced stages of the disease a pure milk-diet, at least during a continuance of the serious symptoms, should be adopted. . . . One of the advantages of milk is its diluent effect, affording solution for the solids and facilitating their removal."

Moderate dilution of milk with Vichy water is, according to Tyson, more beneficial than skimmed milk, and this addition of Vichy is particularly useful whenever there are objections to milk, as it renders milk "more palatable and more easily digested."

3. *Stim'ants.*—As I have said in speaking of chronic parenchymatous nephritis, alcoholic stimulants should be avoided as far as possible. Malt liquors, if, as often occurs, the case be complicated with gout, should be strictly prohibited. The light wines, and especially Bordeaux, or Rhine wine, may occasionally be permitted, but even then they must be sparingly used. In the treatment of uræmia it is often indicated, however, to give the stronger alcoholic stimulants promptly, and with a free hand. Of these gin and whiskey are perhaps the least injurious.

In conclusion, it may be of interest to quote, almost literally, the views of some distinguished modern authors in this matter of the dietary management of chronic Bright's disease:

Senator is of the opinion that meat should be almost completely suppressed from the diet of the albuminuric, while, on the other hand, he recommends a vegetable diet as well as fats. Beaumetz upholds Senator's views in part. Among vegetables he refers to the important rôle of the onion (bulb of *Allium cepa*) in the treatment of albuminuria. Among meats, he is "in the habit of recommending to his albuminuric patients to eat ham or roast pork, and the fatter the better." Senator counsels fish; Beaumetz opposes its use. He also proscribes cheese as being "a highly azotized nutriment."

Dickinson[2] says that in nephritis "spare diet and spring water, clear, may often be found sufficient though simple remedies." In granular degeneration "the food should be as non-nitrogeneous as is consistent with the proper nutrition of the patient. A purely vegetable diet has been tried and found not to succeed, and the anæmic tendencies of the complaint forbid the use of a non-nutritious regimen. At the same time, it is obvious that the patient should be kept upon the smallest amount of animal food upon which he can thrive."

In lardaceous disease "the diet may be more liberal than where uræmia is to be more feared."

Fagge[3] devotes fifty-nine pages to the consideration of Bright's disease, and does not give one word to its dietary management. The editor of Dr. Fagge's treatise merely speaks of the utility of "strict diet," and that is all.

Loomis[4] says: "Milk should be the principal article of diet."

Bartels recommends, in chronic inflammation of the tubules, a milk-diet as essential; in cirrhosis of the kidney, he "advises to sustain the strength by abundant meat, milk, and mixed vegetable dietary. In waxy cases he praises the effect of vigorous diet of meat and milk, with the use of good wine."[1] T. Grainger Stewart[2] found in chronic inflammation of the kidneys "that milk-diet or low diet are better suited to such cases than ordinary or ample diet." In cirrhosis of the kidneys he says that "the diet is a less important element than it is in tubular inflammation. In waxy cases "good nourishment is not contra-indicated by the state of the kidneys." Fothergill's dietary of Bright's disease consists mainly of fat, fish, vegetables, and farinaceous substances.

Delafield[3] writes, in chronic parenchymatous nephritis "improve the digestion." In chronic diffuse nephritis "a regulated diet" is "sometimes of service." In uræmic attacks "the patients must be fed with small quantities of fluid food, or of prepared meat."

Strümpell[4] writes, in subchronic and chronic forms of nephritis a milk-diet is to be carried out as far as possible. In contracted kidney "the diet must be carefully regulated, and must be of scant measure or abundant and strengthening, according to the patient's physical constitution. In these cases, too, milk is the chief food to be considered."

Flint[5] says, in chronic Bright's disease "alimentation should be as abundant and nutritious as the powers of digestion will admit of. Milk may with advantage enter largely into the diet in the different forms of Bright's disease. It is important, if the degree of albuminuria be great or considerable, to make up this loss by a highly albuminous diet," etc.

Further quotations would be tedious.

ON THE TREATMENT OF THE ACUTE STAGE OF TRAUMATIC TETANUS.

By JOHN C. MINOR, M.D.,

NEW YORK.

The treatment of traumatic tetanus is a study in toxicology—a question of poisons and antidotes. For I assume in the outset that the disease itself is, in fact, the manifestation of a poison due to the tetanus germ, and produced by the formation of ptomaïnes as a sequence of its germ origin. The demonstration that tetanus is a blood-disease, infectious and inoculable, the discovery of its germ origin in a bacillus, and, finally, the separation from germ cultures of three or four poisonous substances, or alkaloids, called tetanine, tetano-toxine, and spasmo-toxine, the first of which produces tetanus, the second giving rise to tremors, paralysis, and convulsions, the third inducing heavy tonic and clonic spasms, form a chain of evidence extending from the discoveries of Nicolaiev, in 1884, including the investigations of Carle and Ratione, Rosenbach, Terrari, Hocksinger, and Shakespeare, and bringing the subject down to the analyses of Brieger in 1887. As these facts bearing upon the modern aspect of the etiology and pathology of the disease are all matters of record, and doubtless familiar to most of you, they need not detain us. They serve, however, to substantiate the assertion that in the treatment of tetanus we have to deal with a toxic condition.

The interval between the traumatism and the appearance of tetanus varies from three to fifteen days in the majority of cases, a period of incubation during which we must assume that the peculiar poison of tetanus is being elaborated in the system. Of this process we know as yet but little. The fact that a high temperature destroys the tetanus germ points to a possible local prophylaxis in the

primary dressing of wounds, but we are not prepared to offer an opinion as to the efficacy of our present methods of antiseptic surgery as a means of prevention.

It has been wisely said that the healthy working of a nervous centre requires two qualities, namely, a power to act when called into play and a power of remaining at rest. The one is as necessary as the other. In tetanus this power of remaining at rest is lost. Inaction becomes impossible because excitation is constant, and even when the toxic contractions diminish in force, nervous energy accumulates during the remission, to be discharged later on as a paroxysm of increased tension or spasm. The disease has a duration, in average cases, of three or four weeks. There seems to be a definite limit to the production of toxic material, and the disease "runs itself out" and terminates in recovery under certain conditions. That these conditions are not often fulfilled is shown by the mortality, which Gowers places at nearly ninety per cent., a rate that is a sufficient warrant for better and more systematic methods of treatment. The period of the greatest mortality is during the first week of the disease. Cases that reach the eighth day are likely to reach the fourteenth, and cases that reach the fifteenth day are likely to recover. The fact that the disease is a self-limited one should encourage the hope of a successful treatment, provided the patient can be protected against its force for a definite period, and the mortality lists show that this definite period consists of the first and second weeks of the disease, the acute stage of tetanus. Recovery, therefore, depends mainly upon the treatment during this time.

It is admitted that we can neither eliminate nor destroy the poison of tetanus. The disease once started is beyond the reach of direct methods of antagonism, but when we consider the limitation of the disease, and the fact that its activity is expended upon the cord and medulla, we are led to the inference that if we can so act upon the central nervous system that the force of the disease is spent upon a benumbed tissue, if we can so modify the functions of the cord as to materially diminish its reflex excitability until the nerve-storm has passed, we shall accomplish the plainest and most essential feature of treatment. The problem before us, therefore, is how to put the cord and medulla "in splints," physiologically, to do this in the shortest possible time, and to maintain this condition of modified function for at least two weeks.

Since this treatment demands the heroic use of remedies that are not always safe, even in ordinary therapeutic doses, we must obtain as clear an idea as possible of what the remedies are expected to accomplish, and how far we can venture to use them. I do not believe that it is possible, except by profound anæsthesia, to obtain complete relaxation of all the muscles in the first period of an acute case of traumatic tetanus without incurring as much danger from the remedy as from the disease. The object of treatment is not to abolish the manifestations of the disease, but to control them to such a degree as to maintain a relatively safe condition long enough for the disease to expend itself. This requires a brief consideration of certain clinical features that appear to serve as an index to the effect of treatment, and you will note, of course, that neither the pulse, temperature, respiration, nor pain are accepted as of any special value in this direction while the manifestations of the disease upon the muscular system are emphasized because of their clinical significance. Beginning with mere stiffness of the jaws and neck, the muscular tension increases and involves the muscles of the abdomen and chest. At times a sudden increase in the degree of this tension occurs, as a paroxysm or convulsive spasm, affecting the whole muscular system, producing opisthotonus or other distortions, and threatening death by asphyxia from toxic contraction of the muscles of respiration. This spasm comes like a flash, lasts a few seconds, and is gone. Then the patient returns to the former condition of muscular rigidity, more or less pronounced, lasting a variable time, gradually increasing in degree, and terminating in another spasm. Death, in two-thirds of the cases, occurs in a spasm so prolonged as to asphyxiate. It is to be noted that we have a period of remission and one of exacerbation or spasm, with a certain rhythmic rise and fall of nervous excitability. This condition, during the first or acute stage of the disease, is one of increasing violence. The spasms grow more severe, and the remissions are shorter or less pronounced until in about one or two weeks the disease culminates in a spasm of extreme violence that usually ends the case. But not always fatally, for this may be the critical discharge, from which, if the patient survives, he passes at once into the declining stage of the disease. Other causes of death may occur in the form of simple exhaustion, cardiac failure, or from accidental complications. It appears, then, that in the prolongation of the convulsive paroxysms lies the greatest danger to the patient. Eliminate these spasms from the disease and it would cease to yield such a frightful mortality. This is precisely the aim of our treatment, for the definite purpose in view is to prolong the remissions and modify or absolutely prevent the paroxysms. To accomplish this result we must fully appreciate the fact in therapeutics that when the functions of the nervous system are under the control of any agent that modifies them they are not easily affected by any other agent, or, as Dujardin-Beaumetz puts it, "when a nervous element is influenced or modified by a medicinal agent previously taken it cannot be easily impressed by any other medicament." This is a good rule, for it works both ways. We have, for instance, in tetanus, a toxæmia of which tetanine is the genetic agent. This poison produces a marked influence on the functions of the cord, increasing its reflex excitability. Now, if we attempt to counteract this effect by agents that depress the functional activity of the cord, such as eserine, chloral, the bromides, etc., we shall find that ordinary doses produce little or no effect. The nervous system is already under the control of a powerful modifier of function, and in this case "possession is nine points of the law." Therapeutic doses will be inert, toxic doses will be required to produce therapeutic effects. On the other hand, if we once obtain control of the nervous system and maintain that advantage by using our remedies in doses sufficient for the purpose, neither tetanine nor any other agent will easily regain control of the functions thus modified.

Such, in brief, is the outline of what I conceive to be the leading principles that should govern the treatment of the acute stage of traumatic tetanus. They account for the fact that recovery may occur under methods of treatment apparently diverse in character. Assuming that all remedies useful in the treatment of tetanus must possess the power of depressing the functional activity of the cord, the choice of remedies is not of more importance than the method of using them, and a poor remedy well used is better than the best of remedies inefficiently given.

The selection of agents calculated to fulfil the indications of treatment is a matter that can be determined only approximately by our present knowledge of their physiological action. The main object being to intoxicate the spinal cord so as to depress its normal excitability, it is evident that quite a wide range of drugs are at our service. Whiskey, the bromides, morphine, chloral, calabar bean, veratrum viride, gelseminum, belladonna, cannabis indica, nitrite of amyl, and many other remedies have been used, and used successfully in this disease, but it will be remarked at once that, however much they may differ in their general character and action, in the one essential property of depressing the functional activity of the cord they are all efficient, to a greater or less degree, if properly used. It is not my purpose to enter into a discussion of the relative merits of these drugs. I can only indicate my preference for calabar bean, chloral, and the bromides, with an occasional resort to chloroform, as furnishing all that is necessary for the treatment of the acute stage of the disease. They will serve at least to illustrate, in a

practical way, the main features of the treatment. Each of these remedies appears to have a special place and purpose in clinical use. We may divide the course of the disease naturally into two periods, the period of increase and the period of decline, with the climax or crisis between. Chloroform, calabar bean, and chloral have their most effective use in the first period of the disease and at its crisis. The bromides, and also the salicylates, come into use during the declining period. During the first period there are three indications to be fulfilled: 1st, to lessen muscular rigidity; 2d, to prevent convulsive spasms; 3d, to carry the patient through the culmination or crisis of the disease. To accomplish the first of these, and to maintain this advantage, is to accomplish all. The three remedies already mentioned are not equally adapted to the purpose in view. Chloroform, for instance, has only a limited use, but within its range of adaptation its action is unrivalled. There are two conditions in which its use may be necessary. The first is in those cases of rapid development, occurring soon after an injury, in which the violence of the paroxysms and their frequent recurrence threaten an early and fatal termination. One cause for the fatality of this most acute form of the disease lies in the difficulty of producing any therapeutic action in the presence of so profound a toxæmia. Again, chloroform may be necessary in cases of slower development, in which the disease, either from neglect or ineffectual treatment, has been permitted to get under full headway. Under these conditions chloroform is of immense service. Its action is sure and rapid. Carried to the degree of narcosis it gives us full control of the functions of the cord, abolishes reflex excitability, and holds the disease in check. This point attained, anæsthesia is to be continued long enough to transfer the control of the functions of the cord from chloroform to some other and safer agent. During anæsthesia, then, we may administer chloral, calabar bean, or any remedy suitable for hypodermic or rectal absorption, and, after allowing twenty minutes or half an hour for absorption to occur, suspend the chloroform. The patient gradually passes out from the control of the anæsthetic and into the control of either the remedy or the disease. If a proper dose has been given, the symptoms of the disease will reappear, but in a modified form, the muscles being less tense, and the pain relieved. It now remains to keep up this modified condition with appropriate remedies. Chloroform is no longer needed.

To lessen muscular tension and prevent the occurrence of spasm we may use either calabar bean or chloral, or both. Of the two, calabar-bean is the best remedy, because its action is confined to the same field in which the tetanus poison operates, and it is the nearest approach to a physiological antidote to tetanine that the Materia Medica offers. The variable character of the drug, as usually found, renders it very unreliable in practice, and hence it is better to use the salicylate of eserine than to depend upon the solid extract of calabar bean. Chloral is not so good a remedy, nor so perfect an antagonist of tetanine as calabar bean, but it is a better drug, and practically of great value in tetanus. If calabar bean is used, chloral will be needed to supplement its action as the disease approaches its climax. If chloral is used, the bromides will serve in the same relation. The question of dosage must start with the maximum quantity, and be determined as to its increase by the effect observed upon the muscles. Verneuil, in advocating the use of chloral, advises doses of at least 3 j. to adults, and not less than 3 iv. daily. He suggests immobilization in Bonnet's wire apparatus, and guards against a depression of the temperature by encasing the body in wadding. He considers it necessary to so regulate the dose as to keep the patient in a kind of continuous coma for at least fifteen days, and then to gradually reduce the amount of chloral daily. Meantime proper nourishment must be given and constipation avoided. This is probably the most effective method to follow when chloral alone is used. It depends upon imitating the natural process of sleep, during which the muscular tension in tetanus is always relieved. It covers more ground than the disease itself, for it modifies the cerebral as well as the spinal functions. It interferes somewhat with the process of nourishment, but not to so great a degree as morphine or atropine, and finally, its paralyzing effect upon the respiratory and cardiac centres render its effective use a matter of no small danger. Like all remedies that are of service in tetanus it has its advantages and its dangers, but there is no such thing as a perfectly safe method of treating the disease successfully, and chloral is not so dangerous as tetanus, nor more unsafe than other remedies adapted to its treatment. Twice I have succeeded in carrying cases of traumatic tetanus to recovery with much smaller doses of chloral than Verneuil advises, but I have never attempted to follow his method literally, believing that a semi-coma is not the best condition for the tetanic patient, and that smaller doses are equally effective if combined with or supported by the action of other remedies. It is to be remembered that during the first two weeks of the disease there is a gradual increase in its violence, and that the remedy must be correspondingly increased in amount in order to maintain its control. This will bring us about the end of the first week to consider the danger arising from toxic doses of chloral. In this dilemma, if without materially increasing the dose of chloral the bromides are superadded to the chloral, we shall increase the action of the remedy without adding to the danger of its use.

The use of calabar bean is a very different matter from the chloral treatment, for it requires far more care and attention to detail. The first requisite is a reliable and fresh preparation of the solid extract, or else the officinal salicylate of eserine, which is preferable to the more unstable sulphate. My own experience is confined to the use of the solid extract, and I now refer to the method of using that preparation. Beginning with a dose of not less than $\frac{1}{2}$ a grain of the solid extract, in adult cases, we must determine the repetition of this initial dose by observing its effects. I am quite aware that from $\frac{1}{15}$ to $\frac{1}{8}$ of a grain is the ordinary therapeutic dose, and that even $\frac{1}{8}$ of a grain may develop toxic symptoms. Some allowance must be made for possible idiosyncrasy in the patient, for the strength and freshness of the drug, and for the violence of the attack that is to be met, and smaller doses may be safer to begin with in average cases, but I speak from experience in advising much larger doses than are usually given.

Its action is evident in from ten to fifteen minutes, and is shown by a notable diminution of the rigidity of the cervical and masseter muscles. They feel less tense to the hand, the patient is able to move the parts with greater freedom, and the pain disappears as tension diminishes. The patient can now take food and swallow with comparative ease, and without the danger of producing a spasm.

Relaxation is not complete, the condition is merely one of diminished tension. After one or two hours the tension gradually increases again, the muscles become rigid, the pain of muscular cramp comes on, the risus sardonicus is more marked, the toxic contraction of the dorsal and cervical muscles begins to arch the head backward, and, unless something is done, a convulsive spasm will occur. The thing to do is to administer another dose of the remedy, and to so regulate the doses as to anticipate this condition and thus prevent the occurrence of spasms. I have already referred to the fact that there is a natural remission and exacerbation in the regular course of the disease, but under the use of calabar bean this periodicity becomes more marked because the remedy contributes to a more pronounced remission during its action. Two grains of the solid extract may be sufficient to obtain this relief for two hours at a time during the first week of the disease, but three or four grains will be necessary in acute cases before the end of the second week, and the increasing violence of the disease will bring these doses

closer together. As the crisis approaches, between the danger of the disease and the danger of the remedy the patient is practically "between the devil and the deep sea," for both the remedy and the disease are cumulative in their toxic action. At this stage of treatment we may possibly avoid both dangers by bringing chloral into use and rapidly diminishing the calabar-bean—a point in practice that is worth remembering. But it is not always possible to avoid the issue and hence a few words are necessary concerning the toxic symptoms of calabar-bean.

The first symptom to be noticed is a diarrhœa that is painless or nearly so and is readily controlled by morphine and, less perfectly, by atropine. This symptom is hardly to be classed as toxic for it is quite within the therapeutic range of the drug and is of no special significance. After the hourly administration of large doses without any apparent effect upon the pupils, with no perceptible increase of the lachrymal or salivary secretions, and without developing any toxic symptoms, all at once they appear in full force without a moment's warning and our patient suddenly exclaims that he cannot see and cannot breathe. We find him in a condition of extreme mental agitation, with a rapid, irregular pulse and tumultuous heart action, the pupils contracted to a mere dot, a deadly pallor on his face, and the whole body bathed in a profuse sweat. This, at least, is what happened in one of my cases after the administration of 500 grains during eleven days and 104 grains during the preceding twenty-four hours. In this emergency two remedies are needed as antidotes, atropine and morphine. The antagonism of atropine to calabar-bean depends on its stimulant action on the respiratory centres while morphine is equally efficient as a rapid cardiac stimulant. The dose of atropine should not exceed $\frac{1}{40}$ of a grain, repeated if necessary, for it is possible to increase the lethal effect of calabar bean by too large a dose of atropine. One-fortieth of a grain of atropine and $\frac{1}{4}$ of a grain of morphine was all that my patient received in the way of antidotes, and in less than an hour all the toxic symptoms had vanished, and he made a steady progress to full recovery on chloral, bromides and galvanism.

The disease has its culminating point and, during the period of its increase, no matter what remedy is given it must be increased in dose in proportion to the work it has to do. At last comes the crisis when we must choose between the danger of an excessive dose of our remedy and an excessive dose of tetanine. We choose the first because if toxic symptoms appear we may antidote them with the probability that the disease will have spent its force at this point. To pass this crisis successfully signifies recovery, yet the subsequent treatment often gets all the credit for "it is the last medicine that cures."

Whether we put the whole nervous system to sleep with chloral, or intoxicate the spinal cord alone with calabar-bean, it is good practice to supplement the leading remedy with some other agent as the disease approaches its culmination for the purpose of getting an increased effect without adding to the danger of the treatment.

To use our remedies timidly is to permit the disease to kill the patient. To use them recklessly is to perform that office ourselves. There can be no question, however, that the first of these errors has contributed most largely to the frightful mortality of the disease. It is to be remembered that the responsibilities assumed by the physician in the treatment of traumatic tetanus are precisely the same as those that belong to the surgeon who undertakes a dangerous and difficult capital operation.

In conclusion, I would merely say, in reference to the general management of cases of traumatic tetanus, that rest and nourishment are so important in their relation to the successful issue of treatment, that no matter how careful and thorough the therapeutic methods may be they will certainly fail unless the strength of the patient is properly supported and his nervous system protected against undue excitement. Quiet, rest, and proper nourhisment are absolutely essential for successful treatment.

THE POISON OF TYPHOID FEVER.[1]

By CYRUS EDSON, M.D.,

NEW YORK.

NOTHING is more discreditable to the civilization of the nineteenth century than the existence of typhoid fever.

Wherever men are congregated together in houses and villages, typhoid fever is endemic.

From Greenland to India, from England to China it holds sway. Yet of all diseases it is the most easily preventable, scarcely excepting small-pox.

Careful scientists have isolated its germ and taught us its characteristics. Numerous observers have shown us under what conditions the germ is best propagated, under what circumstances it perishes, and what agents best effect its destruction, yet their teachings seem utterly lost upon mankind, for people go on year after year drinking polluted water and spreading the disease. During the past year I have visited twenty towns supplied by water from dug or driven wells. In every instance the supply was polluted, and in the case of twelve was responsible for an outbreak of typhoid. The other eight were wanting only an initial case to infect the water-supply and cause an epidemic.

After investigation of many cases I have come to the conclusion that typhoid fever is rarely due to any other cause than polluted water, milk, ice, or meat. The first-named is, of course, the most common. I can readily imagine that other means of spreading the disease may occur, and in the course of this paper will instance other possible causes. I assume the following propositions as having been established by Chantemesse, Vidal, Brouardel, and other investigators with whose works you are familiar.

1st. That typhoid is due to a germ, the bacillus typhosus.

2d. This germ is contained in the sputa and stools of typhoid fever patients.

3d. The bacillus typhosus is easily destroyed by disinfection of infected stools and sputa by means of efficient agents, such as heat, mercuric bichloride, and carbolic acid.

No method of illustration is as convincing and striking as that of citing actual examples of the methods by which the disease is propagated. I will, therefore, give you records of a few authentic cases. Each case illustrates a different method of infection.

For the following instance, which shows how a perfectly pure water-supply, through ignorance, may become accidentally infected, I am indebted to Dr. John H. Girdner, of this city, who, a short time ago, had occasion to visit a small town in North Carolina, and while there was asked by a resident practitioner to see some cases of typhoid in the family of a farmer residing in a little settlement near by. The local medical man could not account for the outbreak, and had attributed it to a wave of the disease sweeping over the country. Dr. Girdner's curiosity was excited and he determined, if possible, to ferret out the causes. Of course his first step was to look after the water-supply. This he found was from one source for the entire hamlet—a clear spring, situated at the base of a cliff, perhaps ten feet high, and at such a distance from any source of drainage or privy contamination as to exclude both. Above the spring the cliff levelled off on a stubble field from which a crop of some cereal had been cut and the ground ploughed and harrowed. The direction of the harrow-furrows and the pitch of the surface was toward the spring; a couple of hundred feet to one side, but on a lower level than spring or field, stood the farm-house. Dr. Girdner ascertained that the first case of the disease occurred in this house, and on asking the country physician how the dejecta were disinfected, was told that they were thrown away at a distance from the

[1] Read before the Section on Hygiene and Public Health of New York Academy of Medicine.

house, and disinfection was left to the sun and fresh air. As they entered the farm-house they met an old woman carrying a vessel under her apron. The country doctor was about to stop her, but was restrained by a gesture from Dr. Girdner. She walked to the stubble-field, proceeded until she reached a point just above the location of the spring, then she gave the contents of the vessel a toss, and walked calmly back to the house. Here was the cause of the epidemic. The rain washed the poison down the harrow-furrows into the spring. Another water-supply was obtained, careful disinfection of the stools practised, and no other cases occurred.

A nearly parallel case was that of the Plymouth, Pa., epidemic. Nearly thirteen hundred persons developed typhoid from infection by the typhoid poison from one individual who resided on the bank of a small mountain stream supplying the town with water.

Typhoid fever is most frequently propagated by contaminated well-water. It is safe to say that scarcely a well exists in this country the water from which is safe to drink.

Wells are popular because they are convenient. Almost anywhere a well from ten to forty feet deep will furnish clear, nice-tasting water that will impress an uninitiated observer with its purity. The country well represents a type described in the Bible under the simile of a "whited sepulchre." It is sunk as conveniently near to the house as possible, often under the floor of the kitchen. It is the habit of the countryman to sink another hole, also as conveniently near as possible to the house—his privy. Now the well draws its supply from an inverted cone, the base of which is at the ground surface. The privy, on the other hand, contaminates a cone, the apex of which is near the surface and the base of which is on a level with the bottom of the well. This gives you an idea of how far-reaching privy contamination is as regards well-water.

So many examples of well-water causing typhoid present themselves that it is embarrassing to make a choice for the purpose of illustration. I will take one, however, that occurred in September last, at a New Jersey seaside-resort. A charitable institution, and a most worthy one it is, has a country house at this place. Six of its children came to this city, and shortly after their arrival developed typhoid. I investigated the water-supply of the country branch and found it to be from a well. A sample of the water analyzed by the Health Department chemist was shown to be contaminated by sewage. The location of the well and that of the privy showed the latter to be the source of the contamination. The privy had been the receptacle for typhoid germs from the bowels of a patient sick with the fever about three weeks before the children were affected.

Ice from infected water has been shown, in an able manner, by Dr. T. J. Mitchell Prudden, to be a source of danger. The typhoid germ is not destroyed by extreme cold. The germs that caused the Plymouth epidemic, already referred to, were exposed to a temperature of 22° below the Fahrenheit zero on the banks of the stream subsequently infected by them after a thaw occurred.

I am indebted to Dr. Fordyce Barker for the following account, illustrating the propagation of the disease by ice, though this epidemic, I regret to say, has not as yet been carefully investigated; its facts, consequently, cannot be vouched for by Dr. Barker; nevertheless it is probably essentially true. I only learned of it yesterday, but will take an early opportunity to personally investigate the conditions and data. Twenty-two cases of typhoid fever developed at a popular watering-place in this State during one of last summer's months. It was found that only those who used ice from a lake near by were affected. This ice was cut from a point near the entrance of a sewer that drained the town, or a portion of it. The use of this ice was stopped and the epidemic ceased.

Milk may be the carrier of typhoid germs, and may become infected in two ways.

First, through the water-supply, as the following instance, related to me by Dr. William M. Smith, will show: A country town in this State developed a large number of cases of typhoid fever (nearly two hundred), and investigation showed that only the customers of a certain milkman were affected. His well was examined and found to be contaminated by the drain of a neighbor's house in which a case of typhoid had recently occurred. The milkman admitted washing his cans with the well-water, but it is probable that he was no better than the others in his business, and occasionally utilized his pump for cow purposes. The infection of milk may possibly be accounted for in another way. It is this: The cow may take into her digestive tract the germs of typhoid; she may or she may not develop the disease (that cows are affected with a disorder that resembles typhoid fever is well known); but even if the germ produces no evil effect on the cow, it is a reasonable theory, and I advance it, that cultures of typhoid bacilli may be developed in the intestines of the animal who drinks water infected by them, and that her dung will be thus infected. Now milk always contains an appreciable quantity of cow-dung. I have seen the Lazell separator, a centrifugal machine for skimming milk, remove from one thousand quarts of milk as much dung as one could hold in both hands. This dung is detached from the udder, to which it adheres, by the operation of milking. I intend trying a series of experiments, with the object of demonstrating this theory, and hope to invoke the aid of Drs. Prudden and Biggs, the pathologists to the Health Department.

The point I desire to make in this paper is, that typhoid fever is essentially preventable, because its poison is always tangible and must be taken into the stomach and intestines in order to produce the disease; that, like cholera, it can never infect through the medium of the atmosphere, but must enter the stomach of man in food or drink, or on some infected article placed in his mouth. The strongest arguments advanced against this view have been those made by Volz, Herman Schmidt, Budd, Murchison, and Hutchinson. The latter writer states as follows: "Typhoid fever may be propagated in consequence of contamination of the atmosphere by typhoid poison. This may be the result of allowing the undisinfected stools or linen soiled by them to remain some time exposed to the air, or may arise from pollution of the soil from the same cause, or from defective drainage." He quotes Herman Schmidt, who cites several outbreaks in German garrisons which he believed to be due to soil-pollution where the ground underneath was found saturated with all kinds of impurities.

In one case the water-supply was found impure and cut off, yet the epidemic persisted. He does not state, however, what the water-supply was, or describe that which was substituted in lieu of the one cut off, nor does he in any one of the cases alleged to have been caused by contaminated air describe the water-supply, the ice-supply (if the latter existed), or that of milk. He merely gives the fact that gross defects were found in drainage, or that extremely filthy conditions existed. We acknowledge that atmospheric contamination by the typhoid poison is impossible when we admit, as we do, into our general hospitals cases of the disease, and treat such cases in wards filled with patients sick with other ailments. Here, if anywhere, the atmosphere would become infected were it possible to so infect it. Here, if anywhere, the disease would find suitable subjects to attack. On every side are persons debilitated and bedridden, who would easily develop the fever if the germ were once introduced into their systems. Do they? I have never known a case to be so caused, and I doubt if any of the experienced gentlemen here can instance such a case. Even if you can, it is such a rare occurrence that other causes must be assigned to it.

If atmospheric infection were possible, New York City would have been almost depopulated during the period be-

fore the Health Department was able to effect reform in methods of plumbing. Most houses in those days were charged with sewer emanations, which were poured into them through their defective and trapless pipes. The following table gives the number of deaths caused by the disease from 1866 to 1876, inclusive:

1866 514	1870 422	1874 275
1867 348	1871 239	1875 247
1868 329	1872 364	1876 283
1869 378	1873 294	

This does not show a very powerfully exciting or even predisposing cause. Assuming the average death-rate of typhoid to be twenty per cent., 239 deaths—the smallest number occurring in any one of the above years—would represent 1,195 cases, a sufficient number surely to infect the sewers.

The observers who defend the theory that the disease originates *de novo*, are negligent in respect to description of causes that must be excluded before their theory can be accepted as proven. In his *brochure* on the subject, Dr. Hutchinson, recognizing this fact, expressly states that the theory that the disease originates spontaneously cannot be accepted, because cases on which the theory is based can be accounted for by the proven fact that the germ may be latent for long periods, under certain conditions, awaiting favorable conditions to be fanned into activity.

Hutchinson cites the following instance, recorded by Von Gioth in proof of this:

"To a village free from typhoid an inhabitant returned suffering from the disease, which he had acquired at a distant place. His evacuations were buried in a dunghill. Some weeks later five persons who were employed in removing dung from this heap were attacked by typhoid fever; their alvine dejections were again buried deeply in the same heap, and nine months later one of two men who were employed in the complete removal of the dung was attacked and died." This instance might be taken as showing that the disease can be transmitted through the medium of the atmosphere, but when it is remembered how easy it is by means of infected hands to infect food, and that this was the probable manner of infection, we must doubt this to be a case of atmospheric infection. I believe that typhoid fever, like cholera, is frequently caused by infected hands. A walking case of typhoid fever is likely to leave its traces wherever it goes.

In the act of using paper after defecation the fingers are soiled. The most careful use of paper or cloth scarcely prevents such soiling. The sputa containing the germs, as has been shown by Ludwig Letzench, may also infect the fingers.

Door-knobs, banisters, etc., may receive a sufficient quantity of the poison to infect the hands of those who subsequently touch them, and the germs may thus be transferred to food or drink. Of course, in case of this method of infection, it would be nearly if not quite impossible to trace the mode of infection, though if we reject the theory of atmospheric infection we can account for such cases as the last described in no other way than that of digital infection. The scrupulous care exercised by the surgeon, who cleans and disinfects his hands and finger-nails before an operation, shows his appreciation of digital infection by disease germs.

It has been claimed by competent observers that meat of animals sick with typhoid fever at the time of slaughtering will produce the disease in persons eating it. The epidemic that occurred at Kloten, near Zurich, has been widely quoted in defence of this theory. In 1878 a festival was held at this place, and of the 690 persons who partook of the meat served at the banquet 290 were taken sick with typhoid fever. Three hundred and seventy-eight people who did not attend the feast, but who ate the meat elsewhere were also affected. Besides these, 49 persons who had not eaten the meat were taken ill subsequently, and their illness could be accounted for by infection from the first cases; in other words, they were secondary cases. All sources of infection other than that of meat could be, and were, carefully excluded. The place was free from typhoid, and it was clearly shown that the water did not cause the disease. All persons who ate no meat escaped, as did those who drank sufficient wine to cause them to vomit. All symptoms of typhoid were present, and post-mortem examinations of those who died showed all the lesions of typhoid fever. It was found that forty-two pounds of veal was furnished by a butcher who had taken it from a calf that was moribund from disease at the time of killing. All the meat of this animal was sent to the festival at Kloten, but the liver was sold to a man at the town of Seaboch, and the brain was sent to the family of a clergyman in the same town. The former got typhoid fever, and the entire family of the latter were attacked by the disease. It was also ascertained that another calf, in the hands of the butcher, was diseased, and the veal from this calf was in a decomposed state. All this meat was kept for some time in a refrigerator in the inn at Kloten, where the festival was held, and this refrigerator was found to be in a horribly filthy condition. Some curious facts were noted in this epidemic: The victims had more abdominal pain than is usual in typhoid fever, and the period of incubation was very short, some of the cases developing on the second day, and the majority between the fifth and ninth days. Dr. Hutchinson, to whose article I am indebted for the account I have just given, states that the short period of incubation is characteristic of all cases of typhoid fever caused by infected meat.

During this fall, with the assistance of Dr. Charles S. Benedict, I have investigated 146 cases in this city, between Twenty-third and Forty-second Streets, taken in succession from the records. Of these 72 were out of town during the thirty days preceding the attack, and 34 of the 72 had been in places known to be infected by typhoid. Seventy-five had not been out of New York, so far as could be learned. Of these 75, 17 were traced to recognized causes; 12 were due to the following method of infection, which was discovered by investigation; of these 6 cases of typhoid fever were reputed as occurring in a tenement-house in West Thirty-second Street.

The first case in the house occurred on August 15, and was in the person of an employee of the Department of Public Works, whose duty it was to clean and repair the public sewers. The other cases appeared in from twenty to sixty days after the first. The plumbing of the house was carefully examined, and no defects were found. I visited the premises with Dr. Benedict, and found that the school sink privy in the yard was flushed by means of a branch from the Croton supply-pipe, introduced in such a manner that its mouth was just under the surface of the contents of the sink when the latter was full. On account of the insufficient water-supply a force-pump was provided in the hall of each floor of the house above the first story. No fixtures were placed in the living rooms, the occupants of the different floors being compelled to obtain the water they used from the pumps in the halls. The supply to the school sink was provided with the usual valve to cut off the water, but this valve was always turned on so as to allow a stream of water to constantly flush the sink. When two pumps were being operated at once the suction induced was sufficient not alone to draw from the Croton main, but also to suck a portion of the privy contents into the water-pipes, thus contaminating the water. The amount drawn in was not enough to attract the attention of the tenants by the taste imparted to the water. The other 6 cases attributable to this cause were in a house in West Thirty-seventh Street, and the conditions found were the same as those I have just described. The first case, however, in this latter instance, contracted the disease in the country. No less than eight other houses, the water-supply of which

was thus contaminated, have been found by inspectors of the Health Department, but only in these two instances, so far as is known, has typhoid fever been caused by such conditions.

Four cases of typhoid fever, occurring in boys, during September, who had not been out of New York, investigated by Dr. A. H. Doty of the Health Department, were traced to the following cause: All were in the habit of bathing daily in the East River, near the mouth of a sewer on a line of which several cases of typhoid fever existed. In these cases no other cause could be assigned for the sickness except the one given, which I think is doubtless correct. The 57 remaining cases not accounted for were probably due to infected ice, milk, meat, or to digital infection. You will be interested to learn the relative prevalence of the disease in this city during the fall of 1887 and that of 1888. It is as follows: September, October, and November, 1887, 435 cases, 105 deaths; September, October, and November, 1888, 557 cases, 132 deaths.

The points I have sought to establish may be summed up as follows:

First. Typhoid fever never infects the atmosphere.

Second. Typhoid fever never arises *de novo*.

Third. The causes of the disease, in order of their frequency, are as follows: 1st, infected water; 2d, infected milk; 3d, infected ice; 4th, digital infection; 5th, infected meat.

In this and in other civilized countries laws are enacted for the purpose of protecting the community from the accidental and criminal use of poisons. Yet, while wise law-makers have recognized the necessity for restricting the distribution of those deadly but useful substances produced by man from the universal and mineral and vegetable kingdoms, they have not recognized the thousandfold greater necessity for restricting the distribution, by means of polluted well water, of the more deadly and useless poison which causes typhoid fever.

As I have already said, typhoid fever is pre-eminently a preventable disease. Its poison has been isolated; its characteristics are known. We know how and by what circumstances it is multiplied and propagated. It is well within the bounds of possibility for a person acquainted with these facts to use it for criminal purposes, and to almost defy detection; and yet against this insidious and deadly poison in the hands of the ignorant or careless we have no safeguards. On every side we are exposed to the danger of being infected by such people with the poisonous agent that has for its effects the train of symptoms called typhoid fever.

If in every case of typhoid fever the stools and bedding were effectually disinfected, and the person of the patient after convalescence was also disinfected, typhoid fever would soon cease to exist. Even if these measures are not observed, nevertheless the danger of taking the disease can be reduced to a minimum by such precautions as can readily be taken by any one who knows the characteristics of the poison and utilizes his knowledge to avoid its dangers, such as never drinking well or ice water, avoiding milk that has not been boiled, and by washing the hands before eating.

The death from typhoid fever of those whose negligence or disregard of the known laws of nature indicates stupidity or indifference is a striking illustration of the operation of the law of the survival of the fittest. It should be remembered, however, that this law applies in the economy of nature to the lower animals and not to man, since the distinctive difference between man and the lower animals is found in his ability to adjust his surroundings in conformity to his actual needs and requirements; whereas the animal is unable to do so. We may therefore assume that the human being who ignorantly subjects himself to conditions which menace his life is reduced to a plane with the lower animals since he neglects to provide such surroundings as are conducive to health and longevity. Let the principles of hygiene be carefully taught throughout the country; let ignorance be removed in this manner and typhoid fever will stop its work.

It has been alleged in the public press that the Health Department of this city is doing nothing to prevent the ravages of typhoid. This is not true. Every case of the disease reported is visited, and in tenement-houses instruction is given by competent men concerning disinfection. Disinfectant agents are also furnished. All possible local causes are looked for, and if any are found to exist they are removed. The result is that secondary cases seldom occur.

During the months of September, October, and November ten physicians employed in this work made 2,592 visits to houses containing contagious diseases. This cost the city about forty cents for each inspection. The time taken for many of these visits was not less than an hour, and some took a longer period.

But, gentlemen, I have said all I have to say at present on the subject, and I will close my remarks by reading a poem written years ago by a distinguished gentleman who is present here to-night, and who little dreams that what he perhaps calls a folly of his youth is to be brought back to him now.

THE OLD OAKEN BUCKET.

(As Revised and Edited by a "Sanitarian.")

With what anguish of mind I remember my childhood,
Recalled in the light of a knowledge since gained;
The malarious farm, the wet, fungus-grown wild-wood;
The chills then contracted that since have remained;
The scum-covered duck pond, the pig-sty close by it,
The ditch where the sour-smelling house drainage fell;
The damp, shaded dwelling, the foul barn-yard nigh it—
But worse than all else was that terrible well;
And the old oaken bucket, the mould-crusted bucket,
The moss-covered bucket that hung in the well.

Just think of it! *Moss* on the vessel that lifted
The water I drank in the days called to mind,
Ere I knew what professors and scientists gifted
In the water of wells by analysis find.
The rotting wood fibre, the oxide of iron,
The algæ, the frog of unusual size,
The water, impure as the verses of Byron,
Are things I remember with tears in my eyes.
And to tell the sad truth—though I shudder to think it—
I considered that water uncommonly clear,
And often at noon, when I went there to drink it,
I enjoyed it as much as I now enjoy beer.
How ardent I seized it with hands that were grimy,
And quick to the mud-covered bottom it fell;
Then reeking with nitrates and nitrites, and slimy
With matter organic, it rose from the well.

Oh! had I but realized, in time to avoid them,
The dangers that lurked in that pestilent draught,
I'd have tested for organic germs and destroyed them
With potassic permanganate ere I had quaffed;
Or, perchance, I'd have boiled it, and afterward strained it
Through filters of charcoal and gravel combined;
Or, after distilling, condensed and regained it,
In potable form, with its filth left behind.
How little I knew of the dread typhoid fever
Which lurked in the water I ventured to drink;
But since I've become a devoted believer
In the teachings of science I shudder to think.
And now, far removed from the scenes I'm describing,
The story for warning to others I tell,
As memory reverts to my youthful imbibing
And I gag at the thought of that horrible well;
And the old oaken bucket, the fungus-grown bucket—
In fact, the slop bucket—that hung in the well.

J. C. BAYLES.

THE CLINICAL TESTS OF CHLOROSIS as distinguished from anæmia are, according to Gräber (*Therapeut. Monatich.*, 1887, No. 10), increased alkalescence of blood, normal percentage of blood-cells with diminished hæmaglobin, normal relations of the leucocytes.

THE TRANSPLANTING OF A RABBIT'S CORNEA INTO THE HUMAN EYE.

By JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, AND SURGEON-IN-CHIEF TO THE PRESBYTERIAN EYE AND EAR CHARITY HOSPITAL OF BALTIMORE CITY.

Six months since I transplanted a disk from a healthy rabbit's cornea into the cornea of a patient who had lost sight from the effects of a lime burn. For three years his eyeballs and lids had been united in symblepharon. I had liberated the left eyeball, and on two occasions had dissected away the whole anterior layer of the fleshy cornea with the hope of meeting a transparent portion within. Granulation tissue would soon form again, and a grayish red cornea would finally always remain. He had good light perception but could not get beyond this low degree of vision. An active man, of twenty-nine years of age, he seemed doomed to permanent blindness for the remainder of his life. His constant appeals for further operations, and the desire to have me keep on cutting away the fleshy layers of granulation tissue as often as they formed, induced me to transplant a disk of clear rabbit's cornea into the centre of his opaque one.

By means of Dr. Von Hippel's ingenious instrument I succeeded in trephining the human cornea, through all of its layers, down to the membrane of Descemet. Seizing the edge of the circular-cut piece, I had the satisfaction of drawing it away entire, leaving a clear lining membrane to the anterior chamber of the eye. Through this clear peep-hole vision was at once restored. Into this well from which the trephine had taken the thick plug I inserted a disk of clear cornea cut out from a living rabbit's eye, by the same trephining instrument. The piece fitted perfectly into the hole made for it, as a bung does in the bung-hole of a barrel, its Descemet membrane lying upon the Descemet membrane of the human eye. The closed lid and a compress kept the graft in position. In a very few days the transplanted piece had become thoroughly adherent to the circular incision. From that time the rabbit's cornea has become identified with that of the man.

As to the successful transplantation of a graft there is now no longer a doubt. How the graft would behave in its new relations was the question of importance to the thousands of blind persons anxiously awaiting the final result of such experiments. To become united to the fleshy walls of the human cornea the transparent disk of rabbit's cornea had to become vascular, and necessarily opaque from infiltration. This was an essential part of the curative process, in order to establish union between the graft and its new bed, and to supply nourishment. Had it not occurred, the transferred piece must have sloughed, shrunken up, and fallen out.

It was very interesting to watch these vitalizing changes as they occurred in the graft. When the eye was exposed after five days of bandaging the infiltrated disk graft, so much whiter than the surrounding red fleshy cornea, made the new central plug quite conspicuous. Some days afterward blood-vessels could be traced creeping into the graft from the pannitic margins of the human cornea, and finally the patch became quite pervaded by newly formed blood-vessels. Fortunately it never became fleshy, although the individual vessels of fine calibre, looping over the circular margin at the line of adhesion, could be traced in their meanderings over the surface of the graft. They were directly connected with large feeding vessels in the ocular conjunctiva. In the course of treatment I divided these large trunks so as to cut off the excessive blood supply to the transplanted piece, and have thereby caused a visible shrinkage of the fine red lines in the graft.

After six months the new piece of transplanted cornea retains its distinguishing features, and its outlines can be readily detected. It is grayish in color, with red marginal tracings. No vessels run entirely across the disk. The back and black ground of pupil modifies decidedly the tinting of this central part of the cornea, and becomes more conspicuous monthly as the graft slowly clears up.

Now comes the question of all importance. What good has the patient secured by the experimental transplantation? Fortunately the benefits, even at this early stage of the experiment, are positive. The patient can see large objects ten feet away from him. This amount of sight, already secured, enables him to move about with confidence, when before the operation he dared not move a foot without the aid of a guiding hand. Alone and unattended he can walk for miles along the country roads in the neighborhood of his home. Quite recently he visited the hospital for inspection. Since the operation his whole facial expression is changed from one of permanent anxiety and doubt to one of confidence and cheerfulness. He can already move about with some freedom, avoiding obstacles in his way. He sees persons ten feet off but not yet to recognize them. This of itself is an immense improvement on no sight. Still I see much better things in store for him. From month to month I can mark his improvement in detecting objects which he did not see on a former visit.

This slow progress is perfectly in keeping with the pathology of the cornea. We are accustomed to observe the snail-like progress in cases of interstitial keratitis, and how months always, and even years are required to restore in such cases good sight to blind people. This piece of transplanted cornea is now undergoing the familiar and regular metamorphoses of interstitial keratitis. While the fleshy cicatrical tissue of the cornea can undergo no change for the better, and must ever remain opaque, there is every evidence that the transplanted piece, infiltrated as it still is, will in time give him the peep hole desired, and will restore useful vision to one otherwise doomed to permanent blindness.

The transplanting of a disk of rabbit's cornea for the purpose of rendering the central portion of an opaque human cornea useful is in this case already so much of a success as to warrant its repetition on any suitable case which may present itself. All cases of corneal blindness are not suitable cases for transplanting. Most of such diseased eyes are the sequel of perforating or sloughing ulcers of the cornea, with amalgamation of iris and cicatricial tissue, and with no aqueous chamber. The *sine qua non* of a proper case for operation is a perfect elastic membrane of Descemet, and a normal anterior chamber, filled with aqueous fluid. The lens and iris must also be intact, with a free pupil. For successful transplanting there must be a transparent membrane of Descemet as the foundation upon which to plant the graft. In preparing the eye by trephining this membrane must not be perforated. It must remain perfect so as to retain the aqueous secretion within its proper chamber, and make a barrier, to prevent the displacement of the newly-placed corneal disk by the oozing away of the eye humors.

In the anatomy of the cornea the various layers of which it is composed are much more closely adherent to each other than is the innermost layer of corneal tissue to the elastic membrane of Descemet. In deep ulcerations of the cornea this lining membrane of the anterior eye chamber will so draw upon its loose connections as to form a protruding hernia through the bottom of the ulcer. By the dexterous handling of Dr. Von Hippel's trephining instrument layer by layer of corneal tissue can be cut through without disturbing the lining membrane. By watching the depth and the regularity of the trephining section, as is necessary in opening the skull, the cupping or turning up of the edges of the portion, as freed, will indicate surely when all the layers are cut through. Seizing the loosened plug with a forceps it is much more easily removed as a whole by traction, than brought away piecemeal. Practice on the fresh eyes of slaughtered animals will make the manipulation perfect. The rabbit's cornea is not so thick as the human, but as the whole thickness of it is added to the human Descemet's

membrane, this addition with the slight pushing out of the membrane by the watery contents of the chamber, will bring the surface of the graft on a level with the anterior corneal surface, and insure the nice adaptation of the edges. The two serous layers when juxtaposed one on the top of the other adhere promptly and perfectly.

In suitable cases the transplanting of a disk of clear animal cornea into the centre of an opaque human cornea, is a legitimate surgical operation, promising to give useful vision to blind people. By useful vision I do not mean perfect sight. If sufficient vision is obtained to allow one to guide himself, and to move about in safety without the constant presence of a helper, it is well worthy of an effort to secure. Judging by my experience in watching the slow development of returning sight in my patient, I would say that the little but steady progress in seeing from week to week will, in the course of time, re-establish an amount of vision very enviable to those who have not it. Independence against compulsory dependence in any of the affairs of life is well worth striving for. Useful sight against no sight becomes a precious acquisition. In a certain class of blind persons the transplanting of clear corneal grafts seems to be the only way to attain this much-desired and longed-for blessing.

Progress of Medical Science.

Observations on the Situation of the Apex-beat in Children.—Dr. W. von Starck has made an elaborate investigation of the situation of the apex-beat in children. The following are his most important conclusions: 1. In the first year of life the situation of the apex-beat is frequently indeterminable. 2. It lies without the nipple line in most children up to the fourth year; during the following years less and less frequently in this situation; after the thirteenth year practically not at all. 3. It is found in the mammary line but seldom in the first year; more and more frequently so up to the seventh year; less often again after that age; but at fourteen may again be found there. 4. Within the mammary line the apex-beat is never found up to the second year; seldom up to the seventh year; from nine upward, in the majority of individuals; from thirteen upward, almost exclusively. 5. In the fourth interspace the apex-beat lies almost exclusively during the first year; thereafter less and less often in that situation. 6. The apex-beat is found in the fourth and fifth interspaces, but seldom during the first two years of life; from the third to the sixth year often; thereafter again less often. 7. In the fifth interspace the apex-beat is very seldom situated during the first two years; in the next years more often—from seven onward in the majority of subjects; after the age of thirteen almost without exception there. 8. The apex-beat is very seldom indeed to be found in the sixth intercostal space in children.—*The Practitioner.*

The Infant's Pulse.—Dr. Edwards, in the *Medical and Surgical Reporter*, says that the most marked characteristic of the infant's pulse is irregularity, which occurs whether the child is asleep or awake, at rest or in active movement. Conditions which will hardly perceptibly affect the pulse of the adult will derange the rhythm of the infant's pulse to a marked degree; disorders of digestion, so common in infancy, show marked effect upon the pulse rhythm. Irregularity is also seen during constipation or diarrhœa, and is associated with intestinal worms and with dentition. An important, and as yet unrecorded, difference between the infant's pulse and that of the adult is the fact that in the former there is an entire absence of dicrotism, and it does not appear until the child has reached the tenth to the fourteenth year; the infant's pulse has not the same recoil as the adult's; it has furthermore been demonstrated that blood-pressure in the young is very low, and that dicrotism in the adult pulse is produced by conditions that do not exist in the infant. It is also well known, since Marey demonstrated the fact, that the longer the vessel the greater the dicrotism. Infants present great variability in the size of their arteries; in some of the diatheses the blood-vessels are much altered; for example, rickets is attended by large arteries. On the other hand, the arterial system may be unduly small. The character of the pulse in infants is difficult to describe; it yields readily to the finger of the observer, is small, irregular, and does not present any marked difference between systole and diastole. One observer aptly remarks that the pulse of infants is deprived of sense, rules, or proportion. It is affected by most trivial departures from health. Even a slight accumulation of flatus, for instance, will so alter the pulse that, judging from it alone, one could not avoid concluding that the little patient was the subject of a grave disease. While irregularity in rhythm may be considered one of the normal features of the pulse, it is not so, however, with persistent frequency, which is always a manifestation of cardiac overstrain, no matter how young the child may be; it also occurs in association with anæmia, leukæmia, and malarial intoxication in babes. The frequent action may be constant or paroxysmal in its appearance. Occasionally in infants we meet with exactly the opposite condition, namely, infrequent pulse, which is usually congenital, although the author has several times observed an infrequent pulse associated with the jaundice that is common during the early months of life, and also with renal disorders. The congenital cases are liable to present also evidences of cerebral disturbance, great mental excitement, or epileptiform attacks.

An Alleged New Use for Ether during Anæsthesia.—Dr. H. A. Hare calls attention to the fact that very frequently, during the early stages of the administration of an anæsthetic, the patient forgets to breathe, even before the ability to perceive peripheral irritation is lost. Even later in anæsthesia, when the breathing suddenly ceases, we are accustomed to use cold water externally and to slap the patient with wet towels. Such measures are generally called for hurriedly, and it is not at all uncommon for an exasperating delay to occur before the water arrives. Ether is always at hand, however, and he has found that in a large number of instances, both in man and in the lower animals, the free use of ether poured upon the belly causes so great a shock by the cold produced by its evaporation, as to cause a very deep inspiration, which is often followed by the normal respiratory movements.—*University Medical Magazine.*

Irritable Bladder and Frequent Micturition in Females.—A paper on irritable bladder and frequent micturition in females has been published by Dr. Alexander Duke, ex-Assistant-Master, Rotunda Hospital. In cases where we are able to exclude the urine itself as a source of irritation, as well as uterine disorders, we are obliged to seek for some other cause. In a great number of these cases there will be found an unnatural appearance of the meatus urinarius, the opening being much smaller and rounder, reminding one somewhat of the pin-hole seen in conjunction with conical cervix uteri. This description of case is comparatively easily cured by forcible dilatation of the meatus or urethral canal. Dr. Duke has noticed a rather curious phenomenon to occur during the process, that is, the escape of a considerable quantity of urine when the blades of the dilator are freely opened (and this after the bladder had been but a few moments before fully emptied to all appearance by the catheter), the amount of urine escaping being fully equal in some cases to that previously removed. It has always been a puzzle to him where this urine came from, as the diagnosis of cystocele is a comparatively easy one, and a sacculated condition of the bladder could not possibly exist in all the cases in which he has noticed this peculiarity. Dilatation of the urethral canal is the most useful treatment in all cases when the urine is normal, and spasm and ir-

ritability is complained of. If there is a manifest want of tone in the bladder, a mixture containing tr. ferri muriati, cantharides, and nux vomica has always given satisfactory results. A blister over the sacrum proves valuable in exceptional cases. The galvanic battery is a *dernier ressort*, and gives most satisfactory results in some apparently hopeless cases, one lady patient having worn a urinal for more than five years, night and day, previous to its employment.—*The Medical Press.*

What can we do to Prevent or Diminish Shock.—This question is answered by Dr. Cheever as follows: 1. Wait for reaction. 2. Never neglect to calm those suffering mental shock by a cheerful word and personal presence. 3. Give alcohol, either spirits or wine, a quarter of an hour before the anæsthetic. 4. Make the anæsthesia short; never begin it until everything is ready; suspend it during the less painful dressings. Consciousness returns tardily. We keep up the anæsthetic longer than is necessary. 5. As rapid an operation as can prudently be done. 6. As short a dressing as practicable. 7. As a cardinal point, avoid chilling the patient. To promote reaction after the operation: 1. Persistent and carefully applied dry heat. (Be careful about accidental burns.) 2. Liquid nourishment, combined with a stimulant and a little laudanum by enema. 3. Subcutaneous injection of brandy. 4. Aromatic spirits of ammonia by the mouth. Champagne is sometimes retained when other things are rejected. 5. Black coffee and brandy, the stimulant *par excellence* when it can be retained in the stomach. 6. Quiet; a horizontal, or more than horizontal position; sleep; assurance that all is over and doing well. Modern surgery has won three great triumphs: It has substituted sleep for pain. It averts secondary hemorrhage by the animal ligature. It prevents fermentation by germicidal applications. Can we add a fourth, by stilling the nervous system and averting, or diminishing, secondary shock?—*Boston Meaical and Surgical Journal.*

Saccharine for Ammoniacal Urine.—Dr. James Little, in a paper upon the value of saccharine in preventing the decomposition of the urine in cases of chronic cystitis, states that although it exerts no very marked effect in tubercular cystitis, or in other varieties of the disease not accompanied by alkaline urine, it has been employed with very beneficial effect whenever a highly ammoniacal state of the renal excretion was present. Saccharine, in fact, appeared to act by neutralizing or diminishing the amount of free ammonia in the urine, whether this arose from stricture, paralysis, or prostatic disease. The ammonia being kept down or extinguished by the drug, the affection became manageable under the ordinary treatment.—*Journal of the American Medical Association.*

How Intestinal Tuberculosis is caused by Swallowing Sputa.—Dr. Hosler has published a paper on the infection of the intestinal mucous membrane from the swallowing of tuberculous sputa. In one case, which he treated in hospital, the patient, who was rather stupid, could not be persuaded into ejecting the sputum, but invariably swallowed it, in quantities which other symptoms showed to have been very great. Ten days after his first attack of cough with expectoration, diarrhœa and severe colic came on, which was relieved by opiates and other appropriate remedies, but which, nevertheless, kept on until death occurred in eight days. Distinct signs of tubercle were found in the lung, but in no other part of the body except abundantly in the intestines and the jejunum. Mosler attributes the presence of tubercle in the intestines in all cases more to the swallowing of the sputa than to a general infection. He has not as yet succeeded in producing tuberculosis of the intestines in animals by feeding them on tuberculous sputa and pieces of solid tubercle, but in one case it caused considerable inflammation of the stomach and small intestine. A tonic prophylactic treatment, in the direction of the bowels, is indicated, as tubercle chooses the weakest organ for its development.—*Pacific Record of Medicine and Surgery.*

A Simple Method for the Detection of Lead in Water.—The minutest quantities of lead in potable waters may be detected by a simple method. The apparatus needed is an ordinary tumbler and two perfectly bright and clean knitting-needles. Fill the glass nearly full of the water to be tested and add eight or ten drops of acetic acid, or, in its absence, a teaspoonful of vinegar. If the water be quite turbid, double or even treble this quantity may be used. The needles should be carefully revolved occasionally. If lead be present in the minutest quantity, in the course of a short time dark or black spots will appear upon the needles, and in the course of six or eight hours the entire surface in contact with the water will be covered with a gray coating, the depth of color of which will depend upon the amount of lead in the fluid. From time to time a needle should be withdrawn and examined with a magnifying-glass, if necessary, to determine whether or not a deposit is being formed. The same needle should be withdrawn each time, and one needle should be left in contact with the fluid three or four hours longer than the other. After removal they should be placed in a dust-free box and left for twenty-four hours, as in cases where the amount of lead is exceedingly small a deposit may be formed which cannot be immediately detected, but which after standing for twenty-four hours becomes very perceptible, the color being a yellow or reddish-rellow.—*National Druggist.*

Ergot in Incontinence of Urine in Children.—A writer in the *Medical Analectic* says that he has been using for many years the fluid extract of ergot in the treatment of incontinence of urine in infants and children, and almost regards it as a specific for the disease. He prefers to give it simply, and to treat separately any conditions of the patients that may require therapeutical aid to correct those states of physical debility which either predispose to incontinence of urine or aggravate its presence. He gives to an infant from one to three years old, five to ten drops; and to a patient from three to ten years, ten to twenty drops every three hours. Few children object to its taste, and it should be continued uninterruptedly for two or three weeks, and resumed if the disease should return, in which case the doses ought to be gradually increased.

Race and Insanity.—Dr. H. M. Bannister concludes from a study of this topic that: 1. In the white race the depressive types of mental disease are most frequent in the Germanic and Scandinavian peoples, and the least so in the Celts; the reverse of this appears to be the case as to the exalted or maniacal types. 2. General paralysis is not a disorder from which any race is immune, but one that depends upon causes independent of racial or national peculiarities. 3. The well-known fact that insanity is much more common among the foreign-born than among natives in this country, is not to any great extent explainable by the shipment of the defective classes of Europe to America. The "cranks" and epileptics, and other neurotic individuals do not appear to be represented, in due proportion, even among the foreigners in our asylums. The cause of the excess of the foreign-born insane in this country is, it seems probable, to be looked for mainly in the fact that, supposing the immigration to include only its proportion of persons below the average of mental strength and flexibility, the change of scene and associations, the difficulties of beginning life among them, disappointments, home-sickness, and all other accidents and trials that befall the new-comers, together contribute to break down mentally a vast number who under other circumstances would have escaped, and largely contribute to the mass of insanity in this country.—*American Journal of Insanity.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 5, 1889.

RAILWAY SPINE.

THE subject of the neurasthenic and the hysterical disorders following injuries has been touched upon by French observers, and a summary of their views, by M. Guinon, has been given to our readers under the title of the "Surgical Relations of Hysteria" (see MEDICAL RECORD, December 29, 1888, page 755). A number of monographs have also appeared from German writers bearing more especially upon the topics of railway injuries; one of these is by Strümpell ("Ueber die traumatischen Neurosen," *Berlin klin. Woch.*, 1888). Strümpell makes a distinction between cases in which the patient presents general symptoms not directly related apparently to the local injury and those in whom local phenomena, such as paralyses, contractures, etc., are found. The first form a class of "general traumatic neuroses;" the latter, of "local traumatic neuroses." Among the chief of the symptoms in the general neurosis are peculiar mental disturbances. The patient suffers from depression, and a tendency to hypochondriasis. There is feebleness of will and of memory, irritability, poor sleep, and often frightful dreams. In the gravest cases, according to Strümpell, the condition may end in actual dementia. Besides this, however, there are signs of a general neurasthenic state. There are anæsthesias, retraction of the visual field, disorders of taste and smell, hyperæsthesias at the seat of injury, tremors, and contractures. This is the same condition that French writers call hysteria, though Strümpell prefers not to adopt that name, but considers it a general neurosis peculiar to itself. Whatever name be given, the facts observed are nearly the same. This general traumatic neurosis, according to Strümpell, is incurable. He has seen improvement in many cases, but that is all.

Under the head of local traumatic neuroses Strümpell describes the various symptoms which to the French school are those of hysteria; viz., functional paralyses, anæsthesia, contractures, hyperæsthesia of the injured part, etc. The peculiar mental disturbance is not present. The local disorders, being all functional, are curable.

A recent work by M. Grasset ("Leçons sur l'Hystéro-traumatisme," Montpellier, 1889) takes up this same subject. For Professor Grasset the nervous sequelæ after injuries and shock form a special type of disorder which he calls traumatic hysteria. In this he agrees with Strümpell (except as to the name hysteria), and differs with his Paris colleagues, Charcot and his pupils. Hystero-traumatism, he says, is a general neurosis, affecting more especially cerebral functions, and belonging to the family of hysterias. It is developed by traumatism in predisposed subjects.

Dr. Oppenheim, of Berlin, read an article last year upon the traumatic neuroses before the Berlin Society for Internal Medicine, which he has subsequently published as a separate monograph ("Die traumatischen Neurosen," Berlin, 1887). The work represents a study of cases observed at the Charité Hospital nerve clinic during the past five years, and contains the record and analysis of thirty-three cases. We cannot attempt to give any complete account of the writer's views here. Dr. Tweedy, in the *Dublin Journal of Medical Science*, has made a long and quite complete summary, part of which we reproduce.

"Certain symptoms," says Oppenheim, "are common to all, or at least to the majority of cases of nervous disease consequent on spinal concussion without external injury. These symptoms are chiefly psychic, and belong to the affection, mental depression and irritability occupying the foreground. The mental depression is accompanied by anxiety of mind, the patient's thoughts being always occupied, even in his dreams, with the accident, but is distinguished from pure melancholia both by the abnormal irritability always present, even in persons previously remarkable for their phlegmatic indifference to internal excitations, and by its hypochondriacal character. Severe intellectual disturbance is rare, but the author has seen a considerable degree of dementia with weakness of memory, also cases of hallucination, and even of traumatic insanity, requiring seclusion. Giddiness and cramps, varying between 'petit mal' and true epilepsy, are not infrequent; but care must be exercised in diagnosticating such from purely hysterical attacks.

"In the domain of the special senses, a mixture of hyperæsthesia and anæsthesia, or rather their juxtaposition, is the most frequent characteristic—*e.g.*, hyperæsthetic zones are found in the anæsthetic cutaneous areas; acuteness of vision is lowered, while the eye is extremely sensitive to light; the auditive faculty is lessened on the whole, while certain sounds react abnormally."

An article by Dr. Jacob Wolff ("Ueber Railway Spine," *Deut. Medizinal Zeitung*, October 4, 1888) is rather a review of the subject than an original contribution, and it deals with the organic as well as functional disorders that follow concussion of the brain and spine.

Dr. P. C. Knapp, in an article on "The Nervous Affections following Injury" (*Journal of Nervous and Mental Diseases*, October, 1888, p. 621), goes fully over the various subjects of "railway spine," "railway brain," and spinal concussion. His views incline more toward those of the German writers. "The neurasthenic state," he says, "is often produced by injury, but true hysteria is rare."

There is, he thinks, a fairly typical symptom-complex with psychical disturbances, paræsthesia, anæsthesia, slow and feeble movements, exaggerated reflexes, etc., which is not uncommon, and is probably due to organic disease.

As a result of the various contributions to the subject of traumatic neuroses, one can see that at least some progress is being made in clearing up the confusion which has so widely prevailed regarding this matter. There is,

it seems beyond doubt, a true hysteria sometimes, though rarely in this country, developed after shock; there is oftener, probably, a general neurasthenic state of an irritable form. There is occasionally a peculiar symptom-complex which is almost, if not quite, characteristic of traumatism, which is very serious in character, and probably organic in origin. Finally, it is well known that degenerative changes in the spinal cord and brain can, and do sometimes, follow spinal injury. The French wisely insist that these symptoms can only develop in the predisposed; but their claim that it is all, or nearly all, hysteria, will not hold at all in countries outside of France.

AN OPENING FOR RICH MEN'S SONS.

America, a Chicago journal of excellent literary standing, contains a modest plea for rich men's sons, and in particular sets forth the circumstances extenuating the idleness and folly to which many give themselves up. They are driven to it, we are told, because our institutions close the avenues of employment open to wealthy young men in other countries. The civil service, diplomatic service, and political offices are in the hands and under control of pot-house politicians; the Army and Navy are on so small a footing as to offer opportunity to few, and little inducements to the ambitious.

Without discussing the truth or otherwise of the views set forth in *America*, we would call attention to the fact that the profession of medicine, of all pursuits, just now offers the best inducements and has the greatest need of young men who combine ample means with industry and ambition. The enormous increase in the details and technicalities of medical art, the immense widening of knowledge in every department of our science, makes the acquirement of a thorough, well-rounded medical education a long and expensive process. Our medical schools do not even pretend to do more than send out men equipped in a general way to meet the ordinary accidents, diseases, and natal incidents of life. But the man who aspires some day to be a consultant in the community in which he lives must be thoroughly grounded in pathology; he must know the ordinary technique of bacteriology, urinology, and general histology. He must be able to examine the eye, ear, throat, the nervous system, and all the special organs with a sufficient skill to recognize the presence of anything abnormal. He must learn all these things without flying off into hobbies, and losing his judgment or sense of proportion. He must, therefore, be a man who starts with a good education which has developed his faculties and enabled him to control and use them rationally. He must have studied under a number of teachers, and acquired clinical experience and technical skill in different fields of work.

There is a great need of men of this kind in the profession of medicine. There are few enough now, even in our great cities; and, despite the overcrowding, such workers will find a welcome and sure reward in our ranks. There is no need of specialists; we have too many such already. Specialism, indeed, takes up many men who start out equipped in the way we have indicated, because it has usually been easier and brought pecuniary rewards more quickly. But this is now ceasing to be the case. Specialism is overdone; its ranks overcrowded. The profession needs more of the best quality of scientifically educated general practitioners. There is rich reward for such; and it is a field to which we invite young men of means to devote their energy.

GOOD FORM AND ENGLISH MEDICAL MEN.

THE writer of a recent work on the social customs which guide and illuminate the lives of our English cousins takes up, with other things, the subject of the medical profession. His remarks thereupon are given in another column.

Our readers will learn with interest, perhaps, that the profession of medicine is not one sought by "gentlemen" in England. We had already at times suspected this, although it must be confessed that a number of English medical men who have visited this country have conducted themselves in such a way as to be taken for gentlemen by their American hosts. We are glad, therefore, to find it admitted later that, occasionally and exceptionally, through some freak of fancy or exuberance of scientific bias, "gentlemen" do take up medical studies.

The Philadelphia advocate of an olive-colored button for doctors will be pleased to know that in England this is not necessary, as there is already a "professional garb," consisting of a high hat, light or dark, and a dark coat. This characteristic garb, with the high hat, is to be seen in intense exfoliating luxuriance, in this city on St. Patrick's Day. The high white hat is also, to some extent, an American vice; it is *de rigueur* in the Bowery and at political conventions during the heated spell.

It is not "good form" in England to call a physician "doctor;" it must be "Doctor Jones," or "Doctor Smith." Our informant unfortunately does not say whether it would not be proper to use the favorite American monosyllable, "doc"; or whether such a conjunction as "Doc" Gull or "Doc" Jenner would be in harmony with the best social usages of fashionable London.

The American doctor has some disadvantages to contend against; but it is a great thing that he is an American—a real American—without any hyphen in front, to whom such stuff as is written about the English doctor is meaningless or amusing.

THE NATURE AND TREATMENT OF RICKETS.

AN important and interesting discussion on rickets took place at the meeting of the British Medical Association in August last, a full report of which we find in the *British Medical Journal* of November 24, 1888. The discussion was opened by Dr. W. B. Cheadle, who dwelt more particularly on the etiology and pathology of the disease, and formulated the following general conclusions:

1. It is primarily a diet disease, which can be caused at will by rachitic diet just as certainly as scurvy by a scorbutic diet, and which can be cured as certainly by anti-rachitic diet as scurvy by an anti-scorbutic diet.

2. That the chief defect in diet which causes rickets is want of animal fat.

3. With this, probably, also deficiency of the earthy salts in form of phosphates.

4. A deficiency of animal proteid in conjunction with the preceding intensifies the condition.

5. The rickety state is accentuated by evil external

hygienic conditions, such as foul air and want of light, although these are not essential to its production.

6. Rickets is modified in character by the concurrent existence of congenital syphilis and of scurvy.

In addition to ordinary rickets there are certain aberrant forms, the pathology of which is still doubtful. Most cases of so-called fœtal rickets appear not to be true rickets, but a condition allied to cretinism. Yet there is, *prima facie*, nothing improbable in the commencement of the rachitic state *in utero*. It is possible that, in certain conditions, the mother may be unable to supply the fœtus with the necessary elements. A condition apparently analogous to mollities ossium in adults has been recorded in a child of eight months by Dr. Bury; and Rehn, of Frankfort, has observed a case in which the morbid changes corresponded partly to those of mollities ossium and partly to those of rickets.

Of the so-called "late rickets" or "adolescent rachitis," a condition the existence of which has been denied by some authorities, Dr. Cheadle said he had seen several examples. In one case the disease began in a boy nine years of age, presenting all the symptoms of ordinary rachitis during life, and the osseous changes found post-mortem resembled those met with in the infantile disease.

The treatment, prophylactic and curative, the speaker maintained, was primarily and chiefly dietetic. It was possible, he thought, to absolutely prevent the disease, the only essential condition being that the infant should be placed upon a diet containing in digestible form an ample amount of animal fat with sufficient proteid salts and carbohydrates; in other words, all the elements in the same proportions that obtain in human milk. Drugs were of minor importance, though iron and lime-salts might render good service. Warm clothing, fresh air, and plenty of sunlight were very useful, but nothing would be of much avail without proper food.

Dr. Carmichael was also of the opinion that a proper dietary was an essential factor in the prevention and treatment of rickets, and the fault which he found with most artificial foods was that they were deficient in the fatty element. But he was not disposed to deny the utility of drugs. Cod-liver oil was of great service, but it was often given in too large doses. He had been pleased with the results of inunctions of cod-liver oil, and had used the drug largely in this way.

Dr. Jacobi spoke very highly of phosphorus in the treatment of the disease, having seen very favorable results following its administration. He usually gave from $\frac{1}{150}$ to $\frac{1}{100}$ of a grain two or three times a day.

Dr. Ashby thought there must be some other factor than diet concerned in the production of rickets, for it was not uncommon to find in the same family some children who were healthy and others who were rachitic, all having had essentially the same kind of food. He might have added, indeed, that in some cases the rachitic children had had a more generous dietary than the healthy ones. For it is the younger ones, if any, that are affected, and at the time of their birth the family is often in better circumstances. It is not uncommon to see a young couple who have started in life poor but have prospered as time went on. The first children were brought up in poverty and their food was of the coarsest, but they were vigorous and healthy; when the later children were born the father was well-to-do, and was able to give them food of the most nutritious sort, yet they were evidently rickety. This is seen more especially in large families, and is apparently owing to the fact that the mother has become weakened by long child-bearing, and in consequence the younger children are born weakly and with poor digestive powers. The disease would thus seem to be one due to faulty nutrition, whether in consequence of poor food or of inability to digest and assimilate any food.

Mr. R. W. Parker regarded rickets as an inherited constitutional condition predisposing to disease of systems, manifesting itself in infants as a tendency to catarrh of the pulmonary and intestinal tracts, and of the ventricles of the brain; in young children, as a tendency to disease at the epiphyseal junctions; in older children, in curvature of the long bones; in young adolescents, as a relaxed condition of ligaments, which favored the onset of genu valgum, flat foot, curvatures of the spine, etc. In this sense rickets was a condition which might last from birth up to the seventeenth year of life. It was a condition which nothing explained so well as inherited idiosyncrasy. Diet, he thought, had little or nothing to do with the causation of the disease, although deficient and improper diet might aggravate the condition. As regarded treament, he thought that plenty of fresh air, bathing the body in sea-salt water, with subsequent rubbing and massage, and the use of fresh food as opposed to the prepared foods, would effect a cure, and that drugs might be abandoned.

A DICTIONARY-SUPERSTITION.

A CURIOUS illustration of the propagation of an error through the dictionaries is found in the words "sthenia, asthenia, neurasthenia," etc. According to Dunglison, Webster, Campbell, and, we believe, other authorities, the pronunciation should be on the penult, *e.g.*, neurasthenía, asthenía, myelasthenía, etc. Such pronunciation is quite out of accord with common practice, for the reason that there are scarcely any other words ending in "ia" which are not accented on the antepenult. Diphtheria, neuralgía, dynamía, would sound to everyone like new diseases. There is, in fact, no etymological justification for the dictionary-accents given by the authorities quoted. *Sthenia* comes from σθένος, just as *algia* comes from αλγος. The word σθενεια, from which asthenia and neurasthenia are asserted to be taken, means "a boxing-match," and has no relevance to the words asserted to be derived from it. If, therefore, the physician will simply not give the "e" a long sound he can go on in his old way of antepenultimizing the sthénias, with the consciousness that sometimes man is greater than a lexicon.

DEATH BY DECAPITATION is still recommended by the French medical jurists. In an elaborate work, entitled "La Mort par la Décapitation," by Dr. Paul Loye, the following are given as its advantages: It kills instantly, painlessly, and surely—*tuto, cito, et jucunde*. There can be absolutely no return of consciousness after the blow falls. The separation of the head and trunk offers a public proof of death. In all other procedures, says Dr. Loye, and in death by electricity in particular, the simulation of death is possible.

News of the Week.

THE QUALITY OF ANÆSTHETICS IN NEW YORK.—The chemist of the New York State Board of Health reports that in 1887 there were 326 samples of officinal drugs examined and tested as to purity. The results are not very striking, except as regards chloroform and ether. It was found that safflower is very often substituted for saffron, and that washed sulphur is often impure. Of 53 samples of chloroform, 39 were of good quality, 10 fair, 4 inferior. Of 53 samples of stronger ether, there were 20 of good quality, 5 fair, 26 inferior. Over half the ether dispensed was of bad quality.

RAILWAY TRANSPORTATION AND INFECTIOUS DISEASES.—The National Association of Railroad Baggage Agents have recently met to prepare rules and regulations regarding the transportation of corpses. They have sent to all State boards of health copies of a system of rules prepared by a special committee, with a request that the boards suggest such changes as they see fit. The Iowa board recommended that scarlet fever, typhoid fever, and puerperal fever be added to the list of diseases which render corpses non-transportable; that uniform regulations be adopted regarding disinterment; and that undertakers be compelled to undergo an examination as to their qualifications, and receive a certificate entitling them to engage in business.—*Boston Med. and Surg. Journal.*

DES MOINES, IA., has a crematory for the city refuse which cost only $1,700. As an indication of its effectiveness there was at one time recently burned in it, in one hour, two dead horses, seven dogs, eighteen barrels of garbage, three hods of manure, fifteen bushels of rotten eggs, and three barrels of rotten fish, and no offensive smell was emitted.

THE MEDICAL EXAMINERS of the Boston Life Underwriters held their December meeting at Young's Hotel, December 11th, President G. N. Carpenter in the chair.

THE BENEFITS OF CELIBACY TO ANTISEPTICS.—Antiseptics are, as a rule, better adapted to single than double harness. Corrosive sublimate, for example, butchers bacteria in splendid shape while a bachelor, but sulks when united to most of the other germicides, especially iodine and soap. Carbolic acid has the same antipathy to iodine, but works well with soap, and the two latter make a team when yoked together. Permanganate of potassium is perhaps the most sensitive of all, and resents association with any other antiseptic on the list, but its especial antipathies seem to be carbolic acid, salicylic acid, glycerine, oil, soap, or any organic substance. About all of the combinations that produce results positively innocuous to the most innocent germ on the road are given above. Some of the others are strengthened by union, but, unless the marriage is performed or prescribed by an expert, celibacy is safest.—*Sanitary News.*

CHICAGO is attacking the abortioners, who, it seems, have been doing a flourishing business in that great town.

MUSIC AS A MEDICINE.—While there is not much music in medicine, there is a good deal of medicine in music. The effects of David's music on King Saul are well known. Dr. B. Rush on the "Mind" (Phila., 1825, fifth ed.) says: "Music in hypochondriasis has often afforded great relief." Luther has left the following testimony in its favor: "Next to theology, I give the highest place to music, for thereby anger is forgotten, the devil also; melancholy and many tribulations and evil thoughts are driven away." Dr. Rush says: "I attended a patient who told me that one of his paroxysms was cured by hearing "Old Hundred" sung in a country church. Dr. Cox mentions a striking instance of the power of music over a madman. In this grade the tunes should be plaintive and sedative. Says Dr. Rush (*loc. cit.*): "Certain tones of music have sometimes suddenly relieved a paroxysm of venereal desires."—*Albany Medical Annals.*

ADULTERATION IN THE MANUFACTURE OF IODOFORM GAUZE.—Not long since the attention of the writer was called to a can of iodoform gauze which bore the label of one of the most prominent manufacturers of so-called surgical antiseptic appliances, and upon which it was stated that the contained gauze was treated with thirty-three per cent. of iodoform. He was informed that a careful analysis of the gauze had revealed the fact that it contained but just sufficient of the drug to impart its characteristic odor, and that its beautiful rich iodoform color was due to the fact that it had been treated with a yellow aniline dye. Here was an instance of the grossest mendacity, the risks of which are to be added to the ordinary chances of inefficiency and carelessness in the hands of those to whom are intrusted the preparation of antiseptic materials.—DR. GEORGE R. FOWLER in *Annals of Surgery.*

REVOKING LICENSE TO PRACTISE.—Dr. H. G. Wildman, of the firm Wildman & McCoy, of Chicago, whose license to practise medicine had been revoked by the Illinois State Board of Health on account of alleged unprofessional practices, took an appeal to the Governor of the State, who has now reversed the decision of the State Board.

THE FREQUENCY OF PARASITES IN THE INTESTINAL CANAL is very great in some European countries. At Kiel Heller found some form of parasite in 47.3 per cent. of men, and 49.4 per cent. of women. At Munich, Frierich has found 12.90 per cent. in men, 24.44 per cent. in women. Of these, 6.54 per cent. were lumbricoid worms, 2.80 per cent. oxyuris, and 9.34 tricocephalus dispar.

THE ARRAIGNMENT OF CATGUT.—In the surgical clinic at Berne a series of cases of interrupted healing of wounds occurred, which pursued so typical a course as to suggest to Kocher the existence of a common origin of infection. A total and thorough revision of all antiseptic apparatus and dressings failed to correct the trouble, and thus the question was narrowed down to the catgut used in the clinic. Acting upon this, the catgut was finally excluded from consideration by its complete abandonment, when the usual aseptic course of cases operated upon at the clinic was at once restored. At first, a comparison of cases treated by silk for purposes of both ligature and suture, with those in which catgut was used, demonstrated in a most convincing manner the greater safety of the former as compared with the latter in furnishing immunity from wound-infection, other conditions remaining precisely the same.—DR. GEORGE R. FOWLER in *Annals of Surgery.*

"GOOD FORM" AND THE ENGLISH DOCTOR.—In a work entitled "Good Form in England" we find the following: "The profession of medicine is not one sought by 'gentlemen.' It has been hinted that it requires too much brains and ability. But whether that be the reason or not, it is unquestioned that the 'doctor' in England does not socially hold the position he does on the Continent or in America. . . . No doctor has ever been raised to the peerage. Successful medical men are knighted or made baronets. Brook Street, in London, is the street where fashionable doctors live. Physicians do not have 'offices' in England as they do in America. It would be 'bad form' to speak of going to a doctor's 'office'—his *house* is the proper expression. . . . Physicians and surgeons always wear high hats—black in winter, drab or white in summer—and always a dark frock or morning coat. This is the regulation professional garb. To call a surgeon a 'doctor' would be very 'bad form.' No medical man should be spoken to as 'doctor' without his name also being mentioned, as 'Yes, *doctor*,' 'No, *doctor*,' but 'Yes, Dr. Jones,' 'No, Dr. Smith.' Dentists have no social standing at all in England, and are never by any chance called *doctor*. They are all *misters*. Oculists are not very much better socially."

THE NUISANCE OF ROYAL SURGEONS.—The Duke Charles Theodore, brother of the Empress of Austria, is both oculist and surgeon, and is very skilful; but his fondness for the knife (says London *Truth*) is not appreciated at the Vienna and Munich hospitals, for whenever he operates all the regular arrangements are upset, the whole staff is required to be in attendance on him; he must always be respectfully addressed as "Your Royal Highness," and strict etiquette is observed, all of which is decidedly a nuisance. When the duke is at Vienna, he often passes the whole day in the general hospital, and if there are any arms or legs to be cut off, he hastens joyfully to the work. Duke Charles' zeal may possibly be moderated by his accession to the Bavarian estates of his father, Duke Max, who died the other day. He is married to a cousin of the King of Portugal.

THE INCREASE OF INSANITY IN NEW YORK STATE.—The statistics of the New York State Board of Charities for the year ending October 1, 1888, show only a little increase in the number of the dependent classes other than the insane, and in the expenditures during the year as compared with last year. The whole number of insane in the institutions of the State on October 1, 1888, was 14,772 as against 14,062 on October 1, 1887, an increase of 710, the greatest increase in any year in the history of the State. All of the asylums are full, and many are greatly overcrowded.

CERTAIN ILLINOIS JOURNALS want to abolish the State Board of Health, which, they say, has lapsed into a mutual protective society for the profession of Illinois. To this the *Journal of the American Medical Association* says: "That the tax-payers of Illinois are fully reimbursed for all the expenses of the State Board of Health by what the Board saves to the State in its sanitary work; that in one instance, the small-pox epidemic of 1880–82, the Board caused a saving, outside of Chicago, of 1,517 cases, 320 lives, and more than $2,790,000 (exclusive of actual life-value). Dr. Farr estimated each life as worth $795 to the State; so that the saving in life-value was $254,400; and we thus have a total of $3,044,400 saved by sanitary work at one time, not to speak of what has been done since 1882. In regard to the regulation of medical practice careful estimates show that since the Board has practically cleared the State of itinerants, quacks, and charlatans, two years ago, $450,000 have been saved to the people of the State."

VACCINATION AGAINST CHOLERA.—The practical objection against any form of preventive inoculation against cholera, such as Gameleïa now proposes, is that one attack of the disease rather favors than prevents another.

THE EIGHTY-THIRD ANNUAL MEETING OF THE NEW YORK STATE MEDICAL SOCIETY will be held in the city of Albany, on Tuesday, Wednesday, and Thursday, February 5, 6, and 7, 1889. The following papers have been promised: "The Etiology of Croupous Pneumonia," by Edward M. Sternberg; "A Clinical Study on Alopecia Areata and its Treatment," by L. Duncan Bulkley; "Chronic Headache," by C. L. Dana; "Vertigo—its Causation and Therapeutics," by J. Leonard Corning; "The Medical Treatment of the Diseases of the Urinary Organs in Children," by A. Jacobi; "The Treatment of Typhoid Fever," by S. S. Burt; "Management of Cardiac Dilatation based on its Etiology," by A. L. Loomis; "The Municipal Control of Diphtheria," by Charles Storer; "The Prevention of Summer Diarrhœa among Infants viewed in the Light of the Lesions," by L. Emmett Holt; "Some Sanitary Suggestions," L. E. Felton; "Diagnostic Value of Spinal Rotation," by Bernard Barton; "The Uses of Galvanism in Gynecology," by W. E. Ford; "The Management of Hip-joint Disease," by A. M. Phelps; "Treatment of Hypertrophies at the Base of the Tongue," by W. C. Phillips; "Recent Advance in the Treatment of Hernia," by W. B. De Garmo; "A Plea for the Employment of Koeller's Method," by C. O. Powers; "The Orthopedic Treatment of Tubercular Disease of the Knee in Children," by V. P. Gibney; "A Contribution to the Surgery of Cerebral Tumors," by L. S. Pilcher; "Contribution to Surgery of the Spine," by Robert Abbe; "The Disorders of Menstruation," by Andrew F. Carrier; "The Treatment of Acute Inflammation of the Middle Ear," by Gorham Bacon; "Operative Treatment of an Hyperostosis of External Auditory Canal," by Thomas R. Pooley; "The Use of Prismatic Spectacles for the Relief of Asthenopia caused by Insufficiency of the Ocular Muscles, with Reports of Cases," by D. Webster; "Considerations concerning the Operation for Hard Cataract," by Henry D. Noyes; "Membranous Rhinitis," by Frank H. Potter; "The Spectroscopic Examination of the Blood and Certain Diseases of the Eye," by Lucius Howe; "Purulent Conjunctivitis in Infants and Blindness in New York State," by Lucius Howe. *Titles Unannounced.*—W. S. Ely, George H. Fox, E. Gruening, Edward H. Parker, James R. Hunter. The names of those who have promised to take part in the discussions will be published later. It will greatly facilitate the labors of the Business Committee if members or delegates desiring to read papers will immediately forward their names, with the titles of their articles, to Dr. D. B. St. John Roosa, 20 East Thirtieth Street, New York, Chairman of the Business Committee.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 16, 1888.

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR. CHARLES L. DANA presented a case of

PERIODICAL PARAPLEGIA,

with the following history: M. H——, nine years of age, born in the United States; family healthy. Has been well except for ordinary diseases of childhood. Has had no infectious fevers lately, nor any evidence of malaria, though she lives where it might develop. She is a bright, active girl of nervous temperament, but has never had any nervous or hysterical disorder, or signs of sexual irritation. Present illness began in January, 1888. Since that time she has had six well-marked attacks of paraplegia, lasting from two or three days to two or three weeks. They have occurred approximately on January 1, 1888, lasting two weeks; in March, lasting one week; June, September, October, and on October 23d, lasting two weeks.

The first attack came on in the daytime, three days after a slight fall, by which she bruised her knee. There were no premonitory symptoms. She simply found she could not get out of a chair. There was no pain nor were there any bladder symptoms. Under electrical treatment she recovered perfectly in a fortnight.

The subsequent attacks occurred in much the same way without premonitory symptoms, mental excitement, or any known exciting cause. The child, while playing, would suddenly become paralyzed. The attacks were accompanied with some increased discharge of urine, but with no disturbance of the bowels.

Present attack came on October 23d. The child complained of pain in the feet in the morning, and at about noon could not walk.

When seen by the speaker, six days later, she was paraplegic, could neither walk nor stand, but could move her limbs and flex or extend her feet feebly. She complained of some weakness in the arms. Her feet were extended in equino-varus position, the limbs were somewhat tense and rigid, the knee-jerks much exaggerated, but there was no ankle-clonus. No anæsthesia or tenderness on pressure.

The mother said that the legs had got smaller than they used to be; electrical examination showed some increase of sensibility to galvanic current, but no loss of irritability or changed polar reactions. The patient complained of some pain in the small of the back and abdomen. The mother said that this was the severest attack the child had had. She said the child had no leucorrhœa or sexual irritation, nor any bladder or bowel trouble.

Three days later the patient was far better, and could stand, but still could not walk, and was carried into the clinic. By suggestions and persuasion she was in the course of half an hour got to walk, and did walk out of the clinic with a little help.

Soltmann speaks of temporary intermittent paralysis occurring as the result of sexual irritation, or in hysteria. Kennedy has described temporary spinal paralysis, probably neuritic, however. A number of cases of periodic spinal paralysis have been reported. About one-half were attributed to intermittent fever, the remainder were of idiopathic character. The following are the cases: Fernel, "Universa Medicina," lib. iv.; Cavarré, *Gaz. des Hôpit.*, 1853; Romberg, "Lehrbuch der Nervenheilkunde," 2. Aufl., 752, 753. Hartwig, Halle, 1874; Gibney, *American Journal of Neurology*, 1882, p. 332; Westphal, *Berl. Klin. Wochenschr.*, 1885, Nos. 31 and 32; Fischl, *Prag. Med. Wochenschr.*, 1885, No. 42; Cousat, *Rev. de Méd.*, 1882; Schachkowitsch, *Vratch*, 1882; Greiderberg, *Vratch*, 1887, xxviii. 11; *Centralblat f. Nervenheilk.*, 1888, p. 602; Suckling, *Brain*, January, 1888; Sacchi, *Revista Veneta di Scienze Med.*, 1888. The case was one of periodical hysterical paraplegia. The paraplegic character, absence of sensory or hysterical symptoms, and the periodicity led the speaker to think that such cases were not purely hysterical, however, but that there was a toxic or reflex influence acting as exciting cause of the attacks. Purely hysterical paralyses were usually monoplegic or hemiplegic, with sensory complications.

DR. V. P. GIBNEY referred to a case which he had seen in a child, who had had three or four attacks of paralysis attended by febrile disturbance, which the attending physician regarded as of malarial origin. The patient made a complete recovery, except that there was a condition of hammer-toe remaining. The speaker had searched the medical literature of the Southern States, in which malaria was prevalent, with a view to study the nervous manifestations of this infection, but had not found that brain and spinal-cord lesions were especially prevalent in these regions. He thought it not improbable, however, that the action of the malarial poison in a neurotic subject might declare itself in this manner. In New York City malaria usually assumes a masked form, and he thought it was too much the fashion among physicians to ridicule the term and to call it merely a cloak for ignorance, for he believed that the disease was much more prevalent in this masked form than is generally supposed. He recalled several cases of muscular contractures, which were possibly of reflex origin, but which seemed to be the result of exposure to malarial influences. One case occurred in a colored girl living in Long Island. She had an extreme wry-neck, but recovered completely under the administration of quinine.

DR. G. L. PEABODY related a case of paralysis of both lower extremities occurring in a full-grown woman who had lived in a malarious district. She recovered completely in a few days after being put upon quinine.

DR. CLEVELAND related a case of partial paralysis of the lower limbs in a young girl. The patient could not go upstairs, but could go down. He looked upon the case as a hysterical one, but the parents had the most implicit faith in the child, and would not for an instant have credited such a diagnosis. The treatment consisted in the application of the faradic current, and under this the patient gradually improved, and finally ceased coming. The speaker believed that the reason she got better was because it was too much trouble to make such frequent visits to his office. If it was not a case of hysterical paralysis he was unable to say what it was.

DR. BEVERLEY ROBINSON then opened a discussion (see p. 1) on

THE DIETETIC MANAGEMENT OF BRIGHT'S DISEASE.

DR. A. H. SMITH said that there were two points in relation to the treatment of Bright's disease concerning which he had thought a good deal. The first one was that of the so-called

PHYSIOLOGICAL REST OF THE KIDNEY.

Elimination by the kidneys takes place in two ways; there is, first, a mere transudation of the fluid, and secondly a bursting of the cells, thus allowing the fluid to pass away. Now the question is, do the kidneys do any more work when a larger amount of excrementitious material presents itself for elimination? The speaker doubted very much whether they did. When too much urea is presented it simply is not excreted, and passes along in the blood current in the way that it came. The kidneys excrete what they can, but no more, so that reducing the surplus urea does not afford any rest to the eliminating organs.

The second of the points that had interested him more particularly was

HOW TO MAKE GOOD THE LOST ALBUMIN.

This is a matter of the greatest importance, for the fatal termination of Bright's disease is in many cases fairly at-

tributable to the impoverishment of the blood resulting directly from the draining away of its albumin in the urine. It seems rational, therefore, to supply, if possible, what is lost in this way by a diet containing the material in greater quantity. One should not be misled in the dietetic management of albuminuria by a reasoning based upon the treatment of glycosuria, for the two affections are very dissimilar.

Dr. Peabody said that the practical outcome of Dr. Robinson's remarks was, that we should give to every patient with chronic Bright's disease milk up to the point of toleration. When this point was reached we must experiment with other foods until we found out what kind was best borne by, and most acceptable to, the patient, and had the most favorable influence upon his disease.

Dr. Cleveland said that his experience had led him to think that Dr. Robinson had not expressed it too strongly when he advised a faithful trial of milk diet, for he believed that this, when the patient was able to bear it, was of the greatest benefit.

Dr. Debout d'Estrées said that he had nothing new to add to the discussion on the dietary in Bright's disease, but he wished merely to refer to the fact, which had been not infrequently observed, of the disappearance of albumin from the urine, in cases of Bright's disease, during an attack of gout. An English writer had reported a case in which, in the same individual, having at one time glycosuria, at another albuminuria, the sugar or the albumin, as the case might be, disappeared entirely whenever he suffered from his periodical attacks of gout. The speaker himself had observed the same thing more than once in patients with albumin in the urine.

Dr. Dana referred to the pretty generally accepted belief that uræmic poisoning was due in part to the action of accumulated potash salts, and of the poisonous products of digestion. He thought that this might have a not unimportant bearing on the dietetic management of Bright's disease. Perhaps the employment of sterilized milk and the avoidance of foods containing any ferments, might be of service in these cases. It should not be forgotten that milk is not a perfect food except for growing children; and it should also be remembered that it is a nitrogenous food. His experience had been that the use of milk in large quantity was almost invariably followed by an increase in the amount of albumin in the urine. Meat and malt, and distilled water, or spring water, formed a good substitute for milk as a diet, when some change was indicated.

Dr. F. P. Kinnicutt said that Korkunoff, of St. Peters burg, had shown that the excretion of albumin in chronic nephritis, in individuals kept under as nearly as possible identical conditions, varied considerably from day to day; this diurnal variation he personally had observed, when making some investigations several years ago on the effect of nitro-glycerine on the albumin excretion in chronic nephritis. In his cases, the actual daily excretion of albumin in grains had been determined. This natural (?) variation should be borne in mind in deductions as to the effect of any particular diet in this disease.

Dr. Robinson said that he was often in doubt concerning the proper regimen for a patient suffering from Bright's disease, and he generally followed the plan mentioned by Dr. Peabody, viz., to give milk up to the point of toleration, and then to try something else. This whole question of diet in Bright's disease is one that needs careful study, and no fixed rule can be laid down. A patient, for instance, suffering from enlarged heart and profound anæmia could not stand a pure milk diet, and would be injured rather than benefited by it.

Dr. A. H. Smith said that, in his view, the diet that is followed by the least excretion of albumin in the urine is not necessarily the best one for the patient. When a person suffering from Bright's disease is taken to the hospital we are worried not so much by the large amount of albumin as by the small amount of urine passed. We give milk, and the quantity of urine is increased. Is this in consequence of the milk diet, or is it a mere coincidence?

Dr. J. West Roosevelt made a demonstration of some possible

FALLACIES IN THE PHLOROGLUCINE-VANILLINE TEST

for free hydrochloric acid in the stomach. He had obtained a red color, very similar to that occurring with hydrochloric acid, with solutions of carbonates containing free carbonic acid, and he had also found that free hydrochloric acid, even in fairly large amount, failed to give the reaction in the presence of decomposing bouillon. The reactions of phloroglucine-vanilline with the sulphides and other substances were also shown. The speaker referred to the experiments made by Schaefer with this test in the presence of many of the vegetable acids, and to his conclusions that it was not always satisfactory. Dr. Roosevelt thought that clinicians should not rely too implicitly upon this test, at least until it had been tried more thoroughly and all possible sources of error in its application were known and could be guarded against.

Dr. F. P. Kinnicutt said that Dr. Roosevelt's experiments were of interest. The chemistry employed in examining the secretions and contents of the stomach, probably was not faultless, the results obtained by equally well equipped chemists in various parts of the world being somewhat conflicting. Nevertheless, there was a very general consensus of opinion among the best-known clinicians abroad, as to the clinical value of the tests referred to. Clinical results must be accepted, even if the chemistry by which they were obtained was not without flaw.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

R. C. M. Page, M.D., Chairman.

Dr. J. C. Minor read a paper (see p. 6) on

THE MEDICAL TREATMENT OF TETANUS.

Dr. E. D. Fisher read a paper on

CEREBRAL SYPHILIS.

It was not his intention, he said, to take up the subject of specific tumors or inflammation of the membranes, but to confine his remarks more particularly to disease of the vessels. In speaking of the pathology of cerebral syphilis, he said that, in the tertiary stage, the changes, whether in the form of a gumma or merely affecting the arteries, had unquestionably a specific character; and this led him to believe with Rumpf that the virus itself was still active, and that the changes were not due to the effect of a poison which had expended itself, but left its impress on the system. Also, to sustain this clinically, he felt sure that there were found many cases transmitting syphilis late in the course of the disease, in which these hereditary cases then passed through the same class of symptoms as when the disease was transmitted early in its course.

Meyer considered as almost pathognomonic of syphilis a matting together of the dura and pia, with softening of the cortex, since in pachymeningitis from other causes this rarely occurred. According to Heubner, it was a fact characteristic of the pathological changes in syphilis of the arteries, as distinguished from atheroma, that the large arteries alone were affected in atheroma, and that continuous tracts were involved; while occlusion occurred by thrombosis, and never by a narrowing of the lumen of the artery. The process consisted of a simple hypertrophy, resulting in calcification; there being no new-growth. In syphilis, on the other hand, both large and small arteries were affected; the tendency being, however, toward the small and middle-sized vessels. We might, indeed, have thrombosis; but the marked lesion

was narrowing and final occlusion of the vessels from the extension of the new-growth internally, though rarely in the endothelial lining. The process was rapid, and differed from atheroma in that it was not continuous, but occurred in plaques. Arterial disease might occur entirely independent of gummata, and, according to Down, the vessels of the pia were very frequently involved, leading to softening and atrophy of the cortex. The tendency to the formation of new vessels, with thin walls so characteristic of all granular tissue, was here present; so that we had at first a tissue richly supplied with vessels.

Rumpf placed the origin of the arteritis in the middle coat of the vessels, and insisted on its character of granular tissue similar to that found in all syphilitic growths. He admitted the difficulty of differentiation microscopically from atheromatous arterial changes, but believed that a special bacillus could here be found which was the same for the primary chancre and the late growth. A drawing of his representing syphilitic arteritis, in which the narrowing of the lumen was clearly demonstrated, corresponded very closely to a microscopical section of the basilar artery in a case of Dr. Fisher, the history of which he related at the close of the paper.

In treating of the symptoms of cerebral syphilis, he referred first to the psychical changes often present. While sometimes sudden in their onset, they were more frequently gradual, extending over months, or even years. We noticed a general loss of mental power, the ethical nature seemed to suffer, the memory became weakened, and there was often a feeling of loss of power of performance similar to that met with in neurasthenia of the brain. Insomnia independent of cephalalgia was one of the early symptoms, and always a serious one, and it sometimes had associated with it somnolence, or even stupor. Headache was perhaps one of the most frequent of all the early symptoms. It was, however, if localized, of either a cranial bone or dura lesion. It was very often absent when the lesion was situated in the arteries. The cranial nerves, and especially the third, fifth, and sixth pairs, were early affected, either partially or completely. Hutchinson said that he had never seen the seventh nerve alone affected, and considered this an extremely rare occurrence. He was equally strenuous on the diagnostic value of affection of the fifth, as indicating syphilis.

In arterial disease unassociated with meningitis or tumor, we often found the single paralyses of the cranial nerves. Epileptic seizures were frequently present, and as the inflammation was usually diffuse rather than circumscribed, they were more often general than localized. As regards the condition of the eye, Dr. Fisher called attention to choroiditis and retinitis as indicative of an already existing affection of the cerebral vessels. A cloudiness of the disk, appearances of atrophied spots in the fundus, traces of a past retinitis or choroiditis, and gummatous enlargements, especially involving the terminal arteries, naturally aided in making a positive diagnosis. As a diagnostic point, any interference with vision in a part of the field, or a general loss of acuity of vision in the young, should lead to the suspicion of syphilitic disease of the cerebral arteries.

Paralyses of parts widely separated were strongly diagnostic of syphilis. Also hemiplegias coming on without loss of conciousness, in which the paralysis was preceded by numbness and tingling, and gradually extended from the arm to the leg (especially if there had been previous irritability for weeks or months, impairment of memory, and perhaps headache, confusion of ideas, and somnolence or insomnia), occurring in persons under forty, were probably specific.

DISCUSSION.

Dr. William H. Thomson said that the paper was a valuable contribution to a subject of very great interest, and very great obscurity. The differential diagnosis of the various forms of cerebral syphilis was often a very difficult matter. In the first place, the question arose, Have we syphilis at all to deal with? The nervous symptoms alone were not sufficient to determine this point, and it was necessary, therefore, to make an examination over the body of the patient. There was one mark which he regarded as of considerable importance in this connection, and that was tenderness on pressure at the junction of the sternum with the ensiform cartilage. It was almost uniformly present in syphilitic patients, and its diagnostic value was, therefore, very great. It being reasonably sure that the patient was suffering from cerebral syphilis, it must then be determined whether he had meningeal trouble, syphilitic tumor, or vascular disease. If the latter, we should endeavor to find out what particular form of vascular syphilis was present. Syphilis was to be suspected in any case which was characterized by variableness and inconsistency; in which it differed from other forms of disease. In meningitis, headache was the most marked characteristic. In the second place, we had the gradual development of the symptoms. Thirdly, we should examine the condition of the vessels generally, and see whether they are soft and natural. In syphilitic tumor we had to rely very much on the condition of the eye; and choroiditis was much more commonly present than retinitis. Sluggishness of the pupil, which had been referred to in the paper, he had often noticed, though he had not been aware of its diagnostic significance; and he said he was very glad to have his attention called to this point. Sometimes, with meningitis or tumor, there were symptoms of insanity and epileptiform seizures.

About a year ago, he had been called in consultation in the case of a lady well advanced in years, who was in a comatose condition. There was no evidence of kidney disease, indicating that the trouble was uræmic, and pressure upon the sternum elicited groans from the patient, notwithstanding the coma. Suspecting, therefore, that the trouble was due to cerebral syphilis, he advised specific treatment, and the patient afterward recovered. Yesterday he was called in to see the husband of this lady, a man seventy years of age. About two weeks ago he began to be affected with confusion of speech, great irritability, and motor symptoms. These motor symptoms were not of a paralytic kind, but referable to inco-ordination. Depression alternated with excitement, and he became quite emotional. He also had insomnia at night, and suffered from somnolence in the daytime. Dr. Thomson said that he had very little doubt that this patient was suffering from cerebral endarteritis.

Dr. Landon Carter Gray said that if we started from the prime anatomical lesion of syphilis, the round cell, we could get a better idea of syphilitic developments. It was a characteristic of the syphilitic round cell that it had an enormous vitality. It would live for a long time in the system, and would undergo retrograde metamorphosis without the formation of pus. As long as the cell caused no structural disease by its presence the prognosis was favorable. We did not yet know all the forms of cerebral syphilis, but some of them were sufficiently familiar. There might be in the first place a chronic interstitial encephalitis, scarcely distinguishable from that of general paresis except by its slower progress. Secondly, there was pseudo-encephalitis, in which there was great danger from sudden death. In other cases the disease attacked the arteries. Precisely what the lesion was we did not know, but there did not seem to him to be anything pathognomonic about the affection. Finally, there was an implication of the meninges; (1) of the dura, causing headache; (2) of the pia, involving the cortex.

In the majority of instances it was necessary to make the diagnosis from the conditions found in the brain, rather than from evidences of syphilis derived from other sources; and in a paper which he read last year before the Philadelphia Neurological Society, Dr. Gray said he had cited certain groups of symptoms which might fairly be regarded as indicative of specific infection, although they

afforded only proof amounting to a presumption. These symptom groups were as follows:

1. Quasi-periodical cephalalgia of a peculiar kind.

It was relieved by iodide of potassium and mercury, but not by opium. It might be accompanied by obstinate insomnia and by considerable irritability of temper. In this headache quinine was often of as much benefit as in cases not syphilitic.

2. Hemiplegia under forty years of age.

3. Cephalalgia, followed by hemiplegia, which has a singular relationship to one another, in that the cephalalgia ceases immediately upon the supervention of the hemiplegia, and does not recur.

4. Convulsions in the adults, which have not been preceded by convulsions in infancy, and are not of traumatic or nephritic origin, or due to pregnancy, or in an individual subject to migraine.

5. Symptoms indicative of a lesion at the base of the brain.

Of course, tuberculosis had a predilection for the same site, but it could usually be excluded by the history of the case. Tumors of non-specific origin might also be found there, but usually they are not so diffuse as a syphilitic infiltration, and the specific lesions of this part of the brain are generally preceded by a characteristic cephalalgia.

6. A comatose condition extending over days or weeks, not traumatic, meningitic, diabetic, nephritic, or from typhoid fever.

Dr. C. L. Dana said that the symptomatology of cerebral syphilis was very difficult, but from the contributions that had of late years been made to the subject, we could now form a pretty correct picture of it. The pathology, however, still remained in a very unsatisfactory state. He could not believe that the lesions which are observed were due to Dr. Gray's round cell, since this anatomical factor was common to other conditions and affections. In the cases that he had seen there were four different forms of lesions.

They are: 1, Local hyperæmia; 2, local meningitis and gummatous changes; 3, cranial root neuritis, or neuritis itself; 4, degenerative changes resembling those from other causes.

Dr. Fisher, in the course of his remarks in closing the discussion, said that he had found the tenderness of the sternum to pressure, as pointed out by Dr. Thomson, a valuable diagnostic sign of syphilis. As to the round cell referred to by Dr. Gray, he doubted whether it was of syphilitic origin, and thought if there that was anything specific about the pathogeny of the disease, it was a bacillus.

Tubercle Bacilli in the Sweat of Phthisical Persons.—Dr. Eugenio di Mattei reports in the *Archive prio le Scienze Mediche*, vol. xii., No. 14, 1888, a number of experiments made to determine the possibility of transmitting tuberculosis through the medium of the sweat. In the first series, in which the sweat was taken from the skin without any precautions, numbers of tubercle bacilli were found. In the second series the author cleaned carefully a portion of the integument, covering it subsequently with a glass to prevent possible contamination from the air, and then examined the sweat excreted on this part. Here no bacilli were found, showing that the micro-organisms found in the first instance were deposited upon the skin from the surrounding atmosphere, and that none passed through the sweat-glands.

The Supposed Remedial Agency of the odor of cows and cow-stables in cases of consumption is to be tried at Reinickendorf, near Berlin, on a unique scale, says the *New York Analyst*. A vast circular building has been erected, in the basement of which several hundred cows will be kept, and the odor of the stables will be conducted to the rooms in the upper stories!—*Boston Med. and Surg. Journal.*

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 14, 1888.

W. P. Northrup, M.D., President, in the Chair.

Dr. Sellew presented some specimens illustrating the lesions of

GENERAL TUBERCULOSIS,

taken from a child three and a half years of age, who, up to within four days of her death, though convalescing from whooping-cough, had otherwise been well, with the exception of slight listlessness for about a week. Four days before death she was taken with vomiting and fever, followed by delirium, stupor, convulsive twitchings of the face, slight nystagmus, irregular breathing, and occasionally the "hydrocephalic" cry. Physical examination gave only negative results.

Autopsy.—Twenty-four hours after death. The body was well nourished. There was tubercular meningitis at the base of the brain gluing together the large fissures. Moderate exudation at the base. The convolutions were much flattened. The ventricles were enlarged and contained clear fluid. There were no tubercles found in the lungs. One or two bronchial glands were slightly enlarged and cheesy. The liver and spleen were normal, with the exception of the presence of small tubercles. The kidneys were slightly enlarged and the markings moderately distinct. There was moderate catarrh of the stomach and intestines, but no ulcers.

In connection with this case, it was thought to be of interest to ascertain the frequency with which the brain is involved in cases of acute general tuberculosis, and it was found, by reference to the history of cases at the New York Foundling Asylum, that of fifty-nine cases of general tuberculosis, thirty-nine were associated with tubercular meningitis, while in twenty there was no involvement of the brain. Thus, in about two-thirds of the cases there was meningitis, and in about one-third the tubercles were confined to the other viscera.

Dr. Lewis Hall Sayre exhibited the head and neck of a femur, removed five weeks previously from a boy seven years of age, who was suffering from

HIP-JOINT DISEASE.

Up to the age of four years, the boy had enjoyed perfect health. At that time he had had a severe attack of diphtheria followed by serious inflammation of the eyes, which kept him confined to his room for some time. He also had severe middle-ear disease involving the mastoid process. It was then that the first symptoms of hip disease manifested themselves. The course of the disease was marked throughout by comparatively little pain, although there had been suppuration and abscess formation. When the speaker first saw the boy the thigh was flexed at nearly a right angle with the trunk, and there was a large fluctuating tumor in the neighborhood of the trochanter major. It was decided to operate, both for the purpose of correcting the deformity and of giving exit to the pus. When the capsule of the joint was opened it was found that the head and neck of the femur were carious, and these parts were accordingly excised. The acetabulum was not diseased. At present the wound is completely closed, some motion at the hip is possible, and the boy bids well to make a fair recovery. Had it not been for the deformity which called for operation, this case, the speaker thought, would have done remarkably well without exsection.

Dr. Henry P. Loomis presented a stomach removed from the body of a man who had died from

ACUTE MERCURIAL POISONING.

The man, who was twenty-six years of age, took with suicidal intent ten grains of the bichloride of mercury in a glass of water. Soon afterward he repented of the act and applied for relief at the Chambers Street Hos-

pital. His stomach was syphoned; after which eggs and milk were freely administered. He gradually became weaker, with increased frequency and great feebleness of the pulse, and coldness of the extremities. His pharynx was intensely congested, and he complained of severe pain on deglutition. There was constant pain in the epigastrium, and he complained of a sense of burning and constriction in the throat. He vomited constantly a greenish-colored mucus, occasionally streaked with blood, but at no time did the bleeding amount to a free hemorrhage. His urine was frequently examined and always found normal. The countenance assumed a turgid and anxious expression, and four days after taking the poison he died from exhaustion.

Autopsy.—Fourteen hours after death. The mucous membrane of the mouth, throat, and œsophagus was wrinkled and covered with a white coating. The stomach showed at the cardiac end, along the greater curvature, and especially near the pylorus, dark, mottled, and irregular patches; the rest of the mucous membrane, which appeared normal, was covered with a dark, thick, tenacious mucus. No blood was found in the stomach, but two superficial ulcerations were found near the pyloric valve. Microscopical examination of the irregular patches showed that they were due to capillary hemorrhages in the mucosa. The intestines were normal, with the exception of spots of congestion and ecchymosis in the large intestines. The kidneys were apparently normal, but microscopical examination showed a slight amount of parenchymatous degeneration. The liver was intensely congested, but otherwise normal.

Dr. Loomis also presented a specimen of

ANEURISM OF THE ABDOMINAL AORTA,

from a man fifty-three years of age, who was admitted to Bellevue Hospital in a dying condition. No history was obtainable. The diagnosis of lobar pneumonia was made, and the presence of an aneurism was not suspected. The patient died twenty hours after admittance.

Autopsy.—Thirty-six hours after death. The lower lobe of the right lung was in the second stage of pneumonia. The heart was dilated. There was no valvular change. The thoracic aorta showed throughout its whole extent the evidences of a chronic endarteritis, calcareous plates being scattered in places along its wall. Communicating with the abdominal aorta, just below the cœliac axis, was a sacculated aneurism about the size of a small orange, projecting backward and to the left. The opening into the aneurismal sac measured about an inch across. The sac contained no fibrin or blood; along its lower wall was a calcareous plate half an inch square. The aneurism had given rise to no symptoms during life. The liver was cirrhotic, and the kidneys showed the changes of chronic diffuse nephritis.

Dr. Mendelson asked what seemed to be the actual cause of death in the case of mercurial poisoning.

Dr. Loomis replied that the real cause of death was obscure; the man simply grew weaker and weaker until he died.

Dr. Herman M. Biggs presented a liver removed from the body of a Chinaman who had died in Charity Hospital, which showed the presence in great numbers of

DISTOMA HEPATICUM.

The autopsy had been made only a short time before the meeting, and consequently he had not had time to prepare a full report of the case.

Dr. Biggs also presented a specimen showing

RUPTURE OF THE AORTA.

The patient was a woman, an inmate of the almshouse, who, while sitting quietly, suddenly fell over and died. At the autopsy there was found a rupture of the aorta immediately above the valve. At the seat of rupture the adventitia was found dissected from the media for a short distance, but it was not properly a dissecting aneurism, for the blood had evidently made its way between the media and adventitia at the time the rupture occurred. At the point of rupture the aorta did not seem, to the naked eye, to be diseased, but was apparently unusually thin. There was atheroma, however, in the neighborhood. These cases of rupture of the aorta without previous dilatation were rare.

Another specimen illustrated

ANEURISM OF THE AORTA.

There was a large aneurism of the ascending portion of the arch of the aorta, with dilatation of the arch, and adhesions to the sternum. The man had been a helper in the hospital for some time. He had had no symptoms pointing to aneurism, and the condition was discovered only accidentally. The man died suddenly while at stool. There was no rupture of the aneurism, so that the immediate cause of death was somewhat obscure. Possibly death had resulted from suffocation caused by additional compression of the trachea during the act of straining at stool, as there was marked compression and flattening of the trachea from pressure. The aneurism communicated with the aorta through a large opening. The case occurred in the service of Dr. Janeway.

Another specimen presented was one of

RUPTURE OF AN AORTIC ANEURISM.

The aneurism occupied the ascending portion of the arch of the aorta, and the perforation was the size of a pin-hole. Death did not follow until the expiration of about three-quarters of an hour after the first symptoms of rupture occurred. This specimen was interesting for this reason, as death after rupture of aortic aneurism was usually instantaneous. The lesions found in the aorta were those of acute endarteritis.

The speaker said that he wished to call attention again to the frequency of aortic aneurism as a cause of sudden death. About six months ago he had reported thirty-four cases of thoracic aneurism with autopsies, and had laid especial emphasis upon the frequency of this affection as a cause of sudden death without previous marked symptoms. He thought that its frequency was not appreciated by the profession generally, because these cases did not often come to the autopsy table for examination. They were all coroner's cases, and if there were no suspicious circumstances attending death, the coroner's physician did not usually perform an autopsy, but ascribed death to cerebral hemorrhage or heart disease. In a large proportion of such cases an autopsy revealed an aortic aneurism with or without rupture, or a rupture of the aorta or heart. He had presented two other such cases before this autumn, and the three cases now presented had come under observation during the preceding two weeks. The thirty-four cases presented last spring had, with two or three exceptions, been seen within a a period of about eighteen months. Aside from this point which he wished to emphasize, these cases had some features of especial interest. Many of the cases that he had reported had been seen through the courtesy of Dr. W. T. Jenkins, coroner's physician.

The last specimen presented was one of

ULCERATIVE ENDOCARDITIS,

with perforation of one of the aortic cusps. Long festoons of fibrin were found attached to the valves. An examination for bacteria showed the presence of the staphylococcus pyogenes aureus.

Dr. Mendelson, referring to the cause of sudden death in the case of aortic aneurism without rupture, said that he thought the explanation of death from compression on the trachea was not a satisfactory one. It was hard to suppose that a person would die so quickly, and without a struggle, from simple suffocation. He thought a more rational explanation was that death resulted from paralysis of the heart, due to sudden inhibition from stimulation of the vagus nerve.

Dr. Prudden said that when death resulted from the presence of a foreign body in the larynx, the person often died very suddenly and without a struggle.

Dr. Biggs said that he had seen two or three such cases in children. In one case, death was caused by the lodgement of a collar-button between the two vocal cords, and in another by the presence of a screw in the larynx.

Dr. Mendelson said that this class of cases seemed to him but to prove the point he wished to make, for there were none of the usual signs of death by suffocation present. It was more probable that in them, too, death was caused by the reflex stimulation of the vagus through the laryngeal nerves, and consequent cardiac paralysis by inhibition. In the case of aneurism just described the irritation arose probably from the sudden distention of the sac, caused by straining at stool, stretching or rupturing some of the fibres of the recurrent laryngeal, or other branches of the vagus in intimate relation with the aorta.

Dr. Frank Ferguson presented a specimen of

VOLVULUS.

The patient had been seen by a number of physicians, but it was not thought advisable to operate.

Dr. H. J. Boldt said that the history did not make it clear why an operation was not performed, though he doubted not that sufficient contra-indications were evident to those who had the case in charge. It was a fact, however, that many cases of intestinal obstruction were allowed to go on to a fatal termination, which might have been averted by a timely operation. He had himself never seen a case of "idiopathic" peritonitis, and he believed that many patients, who would almost surely die if medicinal measures alone were relied upon, might be saved by early surgical interference.

Dr. John S. Thacher presented a unique specimen, consisting of

A SAC ENCLOSING THE SMALL INTESTINE,

which was discovered at the autopsy of a man dead of portal thrombosis. Some three years ago the patient had had a hemorrhage from the stomach, and another hemorrhage from the stomach and bowels had occurred about a month before death; otherwise the history was negative. The portal vein was found obstructed by a thrombus, but this had had nothing to do with the other condition. The sac enclosing the intestine was a thick, white, and glistening membrane. The only explanation that suggested itself to the speaker was that a knuckle of the duodenum had in some way been brought to make pressure on a portion of the mesentery; this had yielded a little, making a sort of pouch, and then more of the intestine had followed, the mesentery yielding still further, until in this way a complete sac had been formed.

Dr. Thacher then presented a specimen of

ABSCESS OF THE LIVER.

The patient had been ill for about five months with pains in the right hypochondriac region. At the time of his admission to the hospital he was coughing up some blood and pus, and continued to do so for some time. At the autopsy it was found that the abscess of the liver had ruptured through the diaphragm into the right pleural cavity. The right lung had been almost entirely destroyed by the pus.

Dr. Biggs asked whether the speaker had ever seen abscess of the liver occurring independently of ulceration in the cæcum or other parts of the intestine.

Dr. Thacher replied that he had seen a case of this kind very recently, in which no evidences of ulceration were encountered in any portion of the intestine.

Dr. Ferguson thought that intestinal ulcers were almost always present. Sometimes it would be found that ulceration had existed, but that cicatrization had taken place, so that the evidences of the previous condition would be manifested only on careful search.

Dr. J. S. Thacher reported from the Committee on Microscopy concerning the specimens of inflamed and necrotic lung, and of intestinal ulcers from a child, presented at the meeting of October 24th, by Dr. Holt. Microscopical examination of sections of the lung showed the usual appearances of broncho-pneumonia, with an unusual massing of leucocytes in portions. No bacteria were found.

Microscopical examination of the ulcer of the intestine showed along all of the free border of sections an abundance of bacteria, rod-shaped, many slightly curved, some united so as to resemble spirilla. They appeared uniform, and at the site of the ulcer were found at a considerable depth in the inflamed tissue.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRADSHAW LECTURE AT THE COLLEGE OF SURGEONS: MR. HUTCHINSON ON MUSEUMS; THE SPECIAL VALUE OF EDUCATIONAL AND CLINICAL MUSEUMS—THE DEBATE AT THE PATHOLOGICAL SOCIETY ON THE MORBID ANATOMY AND PATHOLOGY OF CHRONIC ALCOHOLISM: DR. PAYNE'S INTRODUCTORY ADDRESS; SPEECHES BY DR. GEORGE HARLEY, DR. LIONEL BEALE, DR. STEPHEN MACKENZIE, AND DR. MOTT—THE MEDICAL COUNCIL AND ITS RECENT SEVERE ACTION.

London, November 11, 1888.

The Bradshaw Lecture for the present year at the College of Surgeons was delivered on Thursday last, by Mr. Hutchinson, F.R.S. The lecturer selected for his subject "Museums in their Relation to Medical Education and the Progress of Knowledge." By his so doing one was irresistibly reminded of the first Bradshaw lecture delivered within the same walls, in 1882, by Sir James Paget, who, although nominally taking for his subject "Some Rare and New Diseases," really devoted no inconsiderable part of his lecture to a dissertation upon the value of museums and the advantages to be derived from studying in them. Although discoursing upon a similar subject, Mr. Hutchinson's lecture was, as might be imagined, no mere repetition of the address given by his eloquent predecessor, but an original discourse of great value, exemplifying the many-sided nature of the subject. Mr. Hutchinson compared a museum to a library. They were, he said, twin institutions, having for their common aim the advance of knowledge. A library should always partake of the attributes of a museum, and a museum should always be in some sort a library. A museum which did not avail itself freely of the aid of printed descriptions, labels, and catalogues, failed to develop a large half of its uses. From the time of Alexander the Great and Aristotle downward, the collectors of museums had almost always been the prolific writers of books; Aldrovandus and Hunter were good examples of this. In some respects, museums had a great advantage over libraries. Thus a library always contained much less than it assumed, a museum usually much more. Books contained the statements of opinion often mistaken, and narrations of supposed facts which it might be equally impossible to believe or to refute. The specimens in a museum spoke for themselves only, and were open to the freest re-examination; they might teach but little, but they did not lead us astray. The museums of our forefathers were very heterogeneous, and something of this still survived in our present institutions. There was little doubt that in the future the development of special museums and of special departments in general museums would receive greater attention. A neglected

division of the subject was that of educational museums. A museum of reference, one designed to aid the research of the well-instructed who were working for the advance of knowledge, ought to take very different lines from one intended for the education of beginners. Almost all our English museums were as yet museums of reference. We had none which could claim to be designedly educational. This was a great want, not only in professional museums but in those designed for the general public. Neither as regarded general science nor medical pursuits, had we any collections of illustrative objects but such as were so heterogeneous and multifarious as to be very confusing to younger students. Educational museums should contain no mere curiosities, and but few rarities, but should be supplied with good illustrative specimens of common things, not too numerous, and so liberally provided with printed description as to fully explain themselves. The museum for reference had a very different scope, and should aim at a very different standard. Nothing should be too rare or too recondite to be suitable for it. Referring to the work done by Aldrovandus, who employed one painter for thirty years, besides obtaining the help of several of the best engravers of the day, to copy specimens of which he could not obtain the originals, Mr. Hutchinson urged that we should endeavor to complete the splendid collection of the College of Surgeons. By means of the camera we could work with far greater ease than Aldrovandus did. The value of photographic and pictorial illustration was dwelt on at some length by the lecturer, and especially in reference to dermatology. Mr. Hutchinson said he wished to advocate the formation of "clinical museums," viz., museums devoted to the illustration of disease as seen in the living subject. As our ordinary pathological collections exhibited in permanent preservation the treasures of the post-mortem room, so would this display for us those of the hospital ward. It would accomplish this by means of casts, models, portraits, and photographs. While almost all our museums possessed a few illustrations of this kind, in none had anything like completeness been attempted. Such a collection would be useful alike to the student, the practitioner, and the investigator. Though costly, in the first instance, yet when once formed it would, in many of its sections (especially those of photography and portraits), be easily and cheaply copied. The lecturer also referred to the value of making a complete collection of surgical instruments.

At the last meeting of the Pathological Society the debate on "The Morbid Anatomy and Pathology of Chronic Alcoholism" was opened by Dr. Payne. In his address Dr. Payne dwelt at some length on the historical aspects of the question. The sixteenth and seventeenth centuries, he said, saw the rise of morbid anatomy, and it was then that, for the first time, anatomical changes were referred to inebriety. In Harvey's lectures, though there was nothing referring directly to alcoholism, diseased livers, evidently produced by this cause, were described. At the beginning of the eighteenth century distilled spirits began to be generally drunk, and a rapid increase of alcoholic diseases followed. When we came to the era of the rise of pathological histology (from 1850 to the present time), the most conspicuous advance was the demonstration of minute changes in various parts of the nervous system, and the uniformity of the action of alcohol throughout the whole body became manifest. The question of whether alcohol was a poison was discussed, and Dr. Payne said that it was quite clear that it was a functional poison of the narcotic class. Its action on the human body was threefold, viz.: 1, As a checker of oxidation, thus favoring the accumulation of fat and producing fatty infiltration or steatosis in parts naturally disposed to it; 2, as a functional stimulus or (in a larger dose) as a functional poison on the nervous system, especially the brain; 3, as a tissue-poison, destroying the vitality of some tissue-elements and setting up inflammation in others. Generally speaking, the parenchymatous elements, nervous or epithelial, suffered degenerative or necrotic changes, while the connective-tissue elements or stroma proliferated and underwent chronic inflammation. Dr. Payne then proceeded to describe the morbid changes produced by alcohol in various organs.

Dr. George Harley then spoke, and said that although it was easy to describe and to understand the action of alcohol when taken in excess, it was quite another thing when one had to deal with the changes produced by alcohol taken frequently in small quantities. For every drunkard there were fifty others who suffered from the effects of alcohol in one form or other, and among them were persons who had never been intoxicated in their lives. The liver was the organ which was not only the earliest, but the most generally affected by the daily imbibition of small quantities of alcohol, and Dr. Harley showed, from statistics, that in men engaged in occupations in which they were exposed to the temptation of "nipping" the death-rate was higher than in men of the same ages otherwise employed. It was not difficult to understand why the liver was the organ most affected, when it was remembered that alcohol taken into the stomach was absorbed by the branches of the portal vein, conveyed directly to the liver, and had to filter through its tissues ere it could get into the general circulation. He had himself shown, in 1853, that the mere injection of alcohol into the portal vein in dogs was sufficient to cause them to become diabetic in two or three hours. Alcohol acted on the tissues of the body as a chemical poison, and several other illustrations of its mode of action were given. While alcohol was not only a medicine in disease, but a food in health, statistics proved that its prolonged and habitual use in a much smaller amount than was habitually supposed was sufficient to materially shorten life.

Dr. Lionel Beale then showed and explained several diagrams from microscopical sections of hepatic cirrhosis. These appeared to show that what was ordinarily considered as increase of the connective tissues of the organ really consisted of débris of the normal tissue of the gland which had been destroyed.

Dr. Stephen Mackenzie then related the case of a girl, twelve years of age, who was admitted into hospital and found to be suffering from enlargement of the liver. As there were no urgent symptoms she was discharged, no conclusion having been come to as to the cause of the enlargement. Some time later she was attacked with uncontrollable hæmatemesis and died within a week. At the post-mortem an extremely contracted, typically cirrhotic liver was found. No history of consumption of alcohol by the child could be obtained.

Dr. Mott then described the case of a man who was known to be a drunkard, and who died collapsed shortly after admission to Charing Cross Hospital. Fatty degeneration of the ventricular walls of the heart was found after death. Dr. Mott remarked that in looking up the literature of the subject he found that Professor Schrötter (Ziemssen's "Cyclopædia") included alcohol among the poisons causing fatty degeneration of the heart. The discussion was then adjourned. Numerous drawings, specimens, and microscopical specimens illustrating the subject of the debate were on view.

The most memorable event of the recent session of the Medical Council has been their drastic action in removing from the register the names of two medical men who had acted as "covers" to unqualified practitioners. I believe this is the first occasion on which the Council have struck any medical man off the register for the offence in question. Their recent severity will doubtless act as a deterrent to other offenders, though to those whose names have just been removed the president, in announcing the decision of the Council, tempered justice with mercy somewhat by stating that the Council had, on a few occasions, restored to the register, after an interval, the names of persons whose names had been penally removed therefrom.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 16, 1888, to December 22, 1888.

ALEXANDER, CHARLES T., Lieutenant-Colonel and Surgeon. Detailed for duty on Army Retiring Board, to meet at Vancouver Barracks, W. T., at the call of the president thereof. Par. 20, S. O. 292, A. G. O., Washington, D. C., December 15, 1888.

KILBOURNE, HENRY S., Captain and Assistant Surgeon. Detailed for duty on Army Retiring Board, to meet at Vancouver Barracks, W. T., at the call of the president thereof. Par. 22, S. O. 292, A. G. O., Washington, D. C., December 15, 1888.

CARTER, WILLIAM F., Captain and Assistant Surgeon. By direction of the Secretary of War the leave of absence granted, S. O. No. 116, November 12, 1888, Department of Texas, is extended five months. Par. 4, S. O. 292, A. G. O., Washington, D. C., December 15, 1888.

MCCREERY, GEORGE, Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 4, S. O. 265, Headquarters Division of the Atlantic, Governor's Island, N. Y., December 15, 1888.

HOPKINS, WILLIAM E., Captain and Assistant Surgeon. Detailed as member of the Army Retiring Board to meet at San Francisco, Cal., vice Major Henry E. Tilton, Surgeon, relieved. Par. 3, S. O. 294, A. G. O., Washington, December 18, 1888.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 29, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	21	2
Scarlet fever	236	50
Cerebro-spinal meningitis	4	2
Measles	329	16
Diphtheria	160	41
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

A MIXTURE FOR TROUBLESOME COUGH of a violent paroxysmal nature, often met with after influenza, is given by Dr. H. O'B. Deck, as follows:

℞ Cocaine hydrochlor. ..... gr. ii.
Morphinæ sulph. ..... gr. iss.
Ext. glycyrrhiz. liq. ..... ♏ xx.
Glycerini ..... ♏ xx.
Aquæ ..... q. s. ad ℥ iv.

M. Sig.—One dessertspoonful every two hours, till the cough is relieved, then less frequently. To be swallowed slowly.

—*Therap. Gazette.*

THE NAIL-BRUSH AS A SOURCE OF INFECTION.—The *British Medical Journal* has made quite a savage and wanton attack upon the nail-brush. This esteemed article of the toilet is thought by the *Journal* to be a dangerous and dirty thing. Such condemnation applies, of course, only to common and strange nail-brushes used in the hospitals. These may, it is thought, be carriers of infection. The question could be easily settled by inoculating pure cultures with tainted nail-brushes or washings from the same. It is but reasonable to assume at any rate that it would be safer if each surgeon should have his own nail-brush.

THE TREATMENT OF PRURITUS.—Correspondents of *The Lancet* send the following suggestions as to the treatment of this often-intractable symptom:—H. W. J. suggests that an undiscovered diabetes or inflammatory or cystic disorder of the cervix uteri will often render a pruritus vulvæ intractable. Barring these important causes, he should try the fifty per cent. ointment of ichthyol with lanoline. Surgeon, presuming there is no gout or uterine disease, recommends a mixture containing sod. bicarb., mag. sulph, and inf. gent., to be taken three times a day in sufficient quantities to keep the bowels moderately open. Also the following lotion, to be applied on linen cloths three or four times a day:—℞ Liq. plumbi, 1½ drachm; pulv. boracis, 3 drachms; zinci. oxid., 2 drachms; glycerine, 2 ounces; water to sixteen ounces. No alcoholic drink to be taken. Mr. Henry Ryley (West Brompton) has during a practice of thirty years found the disease yield to an outward application of the following:—Liq. plumbi, liq. op. sed. (Battey), ung. cetacei, and pure cream from the cow, of each one ounce. The ingredients must be well mixed and dispensed in a wide-mouthed bottle, to admit the fingers. Mr. J. F. Briscot suggests a systemic examination of the external and internal organs of generation for tinea, animal or vegetable, vascular caruncle, and other possible sources of irritation within the vagina or rectum, and an examination of the rectum. Dr. Thursfield (Leamington) asks if cocaine, either as a lotion or an ointment, has been tried. He suggests that the condition of the os and cervix uteri be ascertained, and that coffee be forbidden. Mr. J. C. Balfour (Redbourne) suggests that relief may be obtained by bathing the parts with a solution of boracic acid in water, or a lotion composed of hydrochloric of morphia, hydrocyanic acid, and water. Bromide of ammonium given at night as a sedative has also been found useful. Mr. H. E. Rowell (East Rudham) suggests, if no cause for the disease can be found, great cleanliness, and a lotion containing glycer. boracis, 2 ounces; water to 6 ounces. He also observes that in the 1888 edition of the "Universal Medical Sciences" a sitz bath of hot salt water (from one to five per cent.) just before retiring and an ointment of cocaine oleate and lanoline to be applied twice a day, are recommended by Piffard. Mr. Percy Newell (Ipswich) recommends a careful regulation of the diet and the use of vinolia. The following lotion is, he says, recommended by Dr. Atthill, in his work on "Diseases of Women":—Acid. carbol., 20 grains; tinct. opii, 4 drachms; acid. hydrocyan. dil., 2 drachms; glycerine, 4 drachms; water to 4 ounces. Mr. J. Wrixon (Watford) says that he has found the following prescription effectual:—Ung. plumb., hyd. nit. ox., and acid. borac., of each 2 drachms; cocaine (1 to 30), ½ ounce; ft. ung. This is to be gently rubbed on night and morning for a month, and the parts bathed in a lotion composed of two teaspoonfuls of borax to a pint of cold water. A strong infusion of green tea is also useful. R. W. W. suggests a trial of the following lotion:—Liq. ammon. acet., 1 drachm; acid. hydrocyan. dil., 1½ drachm; inf. tabaci to 8 ounces. The parts subject to irritation to be bathed two or three times a day. The inf. tabaci to be made by infusing sixty grains of bird's-eye tobacco in boiling water for a quarter of an hour. Ixion recommends vinolia, which, he thinks, will allay the irritation at once. The preparation is said to consist of zinc, antiseptics, etc.

PSYCHICAL SYMPTOMS FOLLOWING A DOSE OF MORPHINE.—Dr. S. H. Scheiber reports the case of a woman, aged fifty-four, who took three-fourths of a grain of morphine for the relief of neuralgia. She became unconscious, and remained so for two days. Upon coming to herself on the third day she could not speak, and later developed alexia and agraphia. There were also hallucinations. On the sixth day a bedsore appeared over the coccyx. This condition lasted for about six weeks, and then disappeared spontaneously, without any special treatment.—*La Riforma Medica.*

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 35, No. 2 NEW YORK, JANUARY 12, 1889. Whole No. 949

Original Articles.

ON CRANIO-CEREBRAL TOPOGRAPHY.

By C. L. DANA, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

THE present article is an endeavor to present in as complete a manner as possible the subject of cranio-cerebral topography. This will include a description of the landmarks, and variations in shape and size of the skull; its vascular supply, together with that of the brain; an enumeration of the cerebral lobes and convolutions; and finally, a systematized description of the methods of locating the position of the fissures, convolutions, and lobes upon the scalp.

There is a great variation in the descriptions of cranio-cerebral topography. Some are incomplete, some are certainly inaccurate. The present great interest in cerebral surgery and localization justifies one in an attempt to secure greater uniformity and completeness in the matter. I have embodied some original observations by myself upon the cranio-cerebral relations in children, and have made studies and measurements of numerous crania, for the determination of certain guides in localization. I have also embodied the results of examinations of the interparietal and anterior occipital fissures in over twenty cerebral hemispheres; and present a diagram of the cerebral convolutions more correct in one or two details, I trust, than those of Ecker, now so widely used.

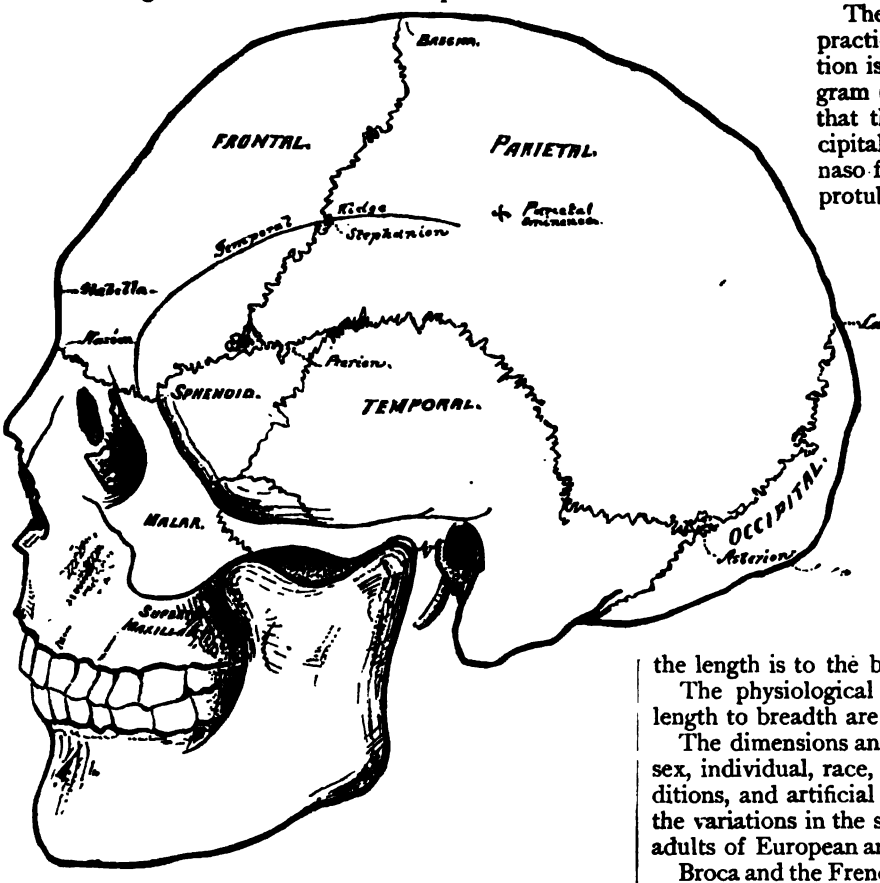

FIG. 1.

The skull landmarks.—There are certain sutures, points of union of sutures, and bony prominences upon the skull not described in ordinary anatomical works, about which it is important to know. The sutures that have to be found for purposes of localization are: The sagittal, the lambdoid, the squamous, the parieto-sphenoidal, and the coronal.

The bony prominences that must be felt are: The external occipital protuberance, or inion, the superior occipital curved line, the glabella, or prominence just above the naso-frontal suture, which latter is called the nasion; the temporal ridge, the parietal eminence, the mastoid process, the external angular process.

The points of union of the sutures have received certain names from Broca. The principal are: The nasion, the inion, the lambda, the stephanion, the pterion, the asterion.

There are others, but these are all of practical importance here. Their position is indicated in the accompanying diagram (Fig. 1). It should be remembered that the inion is identical with the occipital protuberance; the nasion is the naso-frontal junction; the glabella is the protuberance just above the nasion. It should not be confounded with the orbital ridges, on each side. In most descriptions the glabella is given as a landmark of measurement.

DIMENSIONS AND SHAPE OF SKULL.—*General Classification.*—Anthropologists make a general classification of skulls into:

The dolichocephalic, in which the antero-posterior diameter is to the transverse as 100 is to 75, or less.

The brachycephalic, in which the length is to the breadth as 100 is to 80, or more.

The mesocephalic, in which the length is to the breadth as 100 is to 75, to 80.

The physiological limits of variation in the ratio of length to breadth are from 100 to 70, to 100 to 90.

The dimensions and shape of the skull vary with age, sex, individual, race, and with certain pathological conditions, and artificial deformities. In general, however, the variations in the shape and size of the skulls of healthy adults of European and American races are fairly uniform.

Broca and the French anthropologists, Krause, Huschka, Weisbach, and lately Benedict, and the Italian anthropologists, have contributed greatly to our knowledge of these points.

Dr. Frederick Petersen has very carefully abstracted and tabulated the most important of Benedict's measurements, and to these I have added other figures from Benedict and Liharzik [1] (see Table).

The measurements are for the naked skull. The hair and scalp add about six per cent.[2] for surface measure-

[1] In twelve skulls which I measured in this city the naso-occipital arc ranged from 30 to 32.2 ctm,

[2] This amounts to about 3 ctm. in the naso-occipital arc.

Table of Cranial Measurements in Centimetres.

	Adults.		Physiological variation.	New-born.		End of 1st year.		1st to 7th year.		10th year.		7th to 18th years.	18th to 24th years.	End of 12th yr.	
	M.	F.		M.	F.	M.	F.	M.	F.	M.	F.				
1. Greatest circumference.	52.0	50.0	48.5 to 57.4	34.0	34.0	42.0	42.0	34 to 46	....	49	47	46.0 to 49.5	49.5 to 52.25	....	Taken around glabella and maximal occipital point.

Brachy-cephaly	.....	.....	80.0 to 84.9												
Eury-cephaly	.....	.....	over 100 to 150												

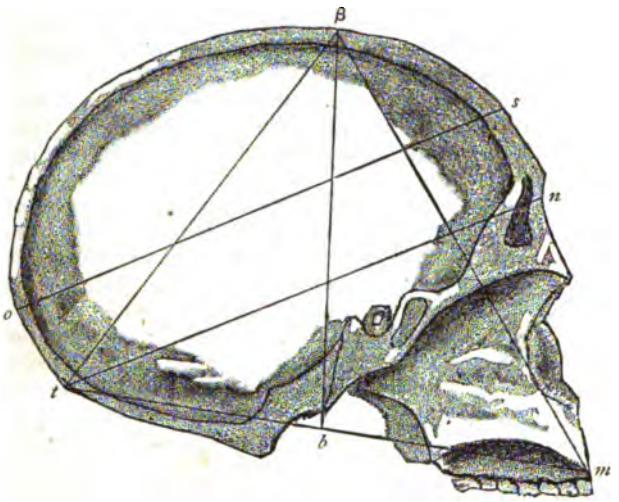

FIG. 2.

ments, and about two per cent., or 1 ctm., for total diameter measurements, the scalp being about 5 mm. ($\frac{1}{5}$ in.) thick.

Variations dependent upon age.—The proportions of the skull change most considerably in the first year, and continue to change up to the fourth year. After that modifications are slight in amount and appear more slowly. By the end of the seventh year the skull has nearly reached its full size (see Table), more nearly in girls than in boys. The chief measurements during childhood are given in the table. The protuberances and ridges are less marked in children.

The orbital index, *i.e.*, rates of height to width of orbit, undergoes great changes during growth. In young children it is 100, *i.e.*, the height and breadth are equal. In adults it is 84.6 (Weisbach), *i.e.*, the breadth is a fifth greater than the height. The naso-bregmatic arc is relatively smaller.

The sexual differences in skulls have been formulated by Broca. He shows that these differences are not absolute, some female skulls having a masculine type, and *vice versa*. The distinctions he lays down are not all of surgical importance. The bony ridges and protuberances are less marked, more particularly the glabella or nasal boss, which in many female skulls is absent.

The inion is also less prominent. Benedict states that there is a concave curve between the orbital borders just above the glabella in man, but not in woman.

The volume of the female skull is less than that of the male, as a rule; but this does not serve as any definite guide in distinguishing the two. The orbital index is greater in woman than in man (Weisbach). In adults the average is 84.6 (in Germans). In men, it is 82.5, in women, 87.8. In other words, women have relatively narrower orbits (Zuckerkandl), corresponding to smaller frontal lobes.

The posterior half of the naso-occipital arc is greater relatively in woman. The lambdo-occipital arc, indeed, is actually absolutely longer in woman. (Benedict's figures.[1] See table.) The cephalic index is greater in women (Germans), *i.e.*, their skulls are relatively broader. The empirical greatest height is relatively much lower in women; in other words women (Germans) have lower as well as broader skulls.

To sum up, the female skull is larger posteriorly, is broader, lower, with higher orbital diameter; often it has no glabella, no super-glabellar depression, and is less well marked as to its ridges, prominences, and sutures.

Variations as regards race.—The length-breadth index and other cranial indices, and the volume, are the only racial differences so far extensively studied. Even these are too indefinite factors to be of any practical value. In general we may say that the Dolichocephalic or long-headed,[2] are the English; Irish; Scandinavians; Negroes, 73; Arabs, 74; Chinese, 76.

The Brachycephalic, or broad-headed, are the Germans, 81; Russians; Turks, 81.

The Mesocephalic, or medium-shaped heads, are the American Indians, 79; Hollanders; Parisians, 79.

The variations dependent upon artificial deformities, accidents, perversions of growth and development, and upon disease.—There are certain individual, more or less pathological variations in the shape of the skull, due to a premature ossification of a suture, or arrest of development in a centre of ossification, or a hyperplasia, or aplasia of a part of the skull or of its contents. When one part is shut off from its natural expansion, other parts, as a rule, undergo compensatory development. This principle underlies the pathology of cranial deformities.

Those deformities which it would be well to look for before mapping out a skull are the:

1. Triangular, or trigonocephalic skull.
2. The keel-shaped or scaphocephalic skull.
3. The acrocephalic skull.
4. The oxycephalic or steeple-shaped skull.
5. The flat-headed skull.
6. The plagiocephalic or obliquely deformed skull.

Variations in the insane, criminal, epileptic, and other psychopathic classes generally.—Minimal measurements of the frontal arc (n β) are oftener found in insane and criminals.

[1] Other figures, such as those given by Krause, Anatomie, ii., p. 55, make the difference less, *e.g.*, male and female both measure 6.6.

[2] The figures are chiefly from Broca; and from Weisbach, in Krause's Anatomie, iii., p. 6, etc.

The parietal arc is also said to be often shorter in the insane, defective, and delinquent classes, and in epileptics.

In these classes, however, maximal excesses also often occur.

There is, as yet, no acknowledged special variation or type which is, of itself, an indication of a peculiar mental trait or specific pathological condition, although Lombroso and his followers have tried to make out such. On the whole, it is found that pronounced deformities occur often in healthy persons, while in psychopathic classes and

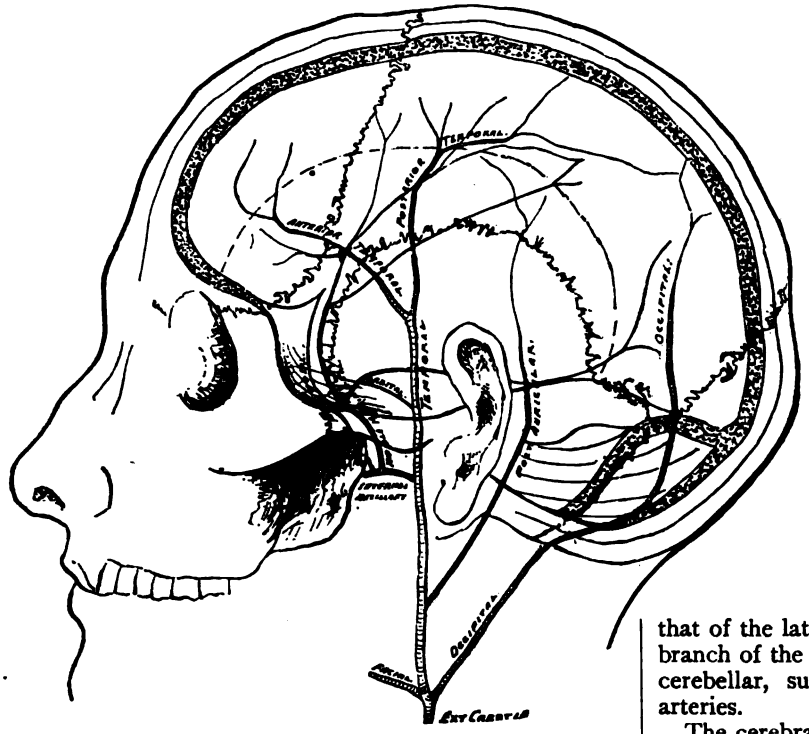

FIG. 3.

criminals there is a large proportion of slight variations, generally minimal, from the normal type.

The vascular supply of the scalp, skull, and brain.—The vascular supply of the scalp, skull, and dura mater comes from the external carotid; that of the eye, brain, and pia mater from the internal carotid and vertebral. The arrangement is shown here:

External carotid		Occipital, inferior meningeal, arteries.
		Posterior auricular.
	Temporal	anterior.
		middle.
		posterior.
		Ascending pharyngeal, posterior meningeal.
		Internal maxillary, middle meningeal, small meningeal.
Internal carotid		Anterior meningeal.
		Anterior cerebral.
		Middle cerebral.
		Posterior communicating.
		Anterior choroid.
Vertebral		Posterior meningeal.
		Inferior cerebellar.
Basilar		Anterior cerebellar.
		Superior cerebellar.
		Posterior cerebral.

The general arrangement and distribution of the arteries of the scalp and dura is shown in the accompanying diagram (Fig. 3). The arterial supply of the scalp is very rich, but it all comes from below; consequently a tight elastic bandage tied around the head, in a measure, stops the circulation above, and sometimes enables the surgeon to operate bloodlessly.

The veins of the convexity of the scalp carry the blood down into the external jugular, except in the occipital region. The occipital vein general ends in the internal jugular.

The nerves of the scalp are the sensory branches of the fifth, viz., the supra-trochlear and supra-orbital, temporo-molar, lachrymal and auricular temporal, the great and small occipital, and great auricular branches of the cervical nerves.

There are motor fibres to the temporal muscle from the fifth, to the occipito-frontalis from the seventh, and from the cervical nerves. No especial harm occurs if any of these nerves are cut.

The blood-supply of the skull is furnished chiefly by the meningeal arteries of the dura mater. These all come, except the small anterior meningeal branches and a small posterior branch, from the external carotid. The blood passes into the diploic veins, and from there passes chiefly into the lower occipital and lateral sinuses. Some of it, however, returns in the venæ comites. It all returns down toward the base of the skull. The arteries are indicated in the table (see also Fig. 3).

The most important of these arteries is the middle meningeal, both on account of its size and its distribution over important functional areas. The position of this artery is shown in the figure. A large branch grooves the anterior inferior end of the parietal bone and passes up close to, but usually just posterior to, the coronal suture.

The blood-supply to the brain comes from the internal carotid and the vertebral arteries. The branches of the former artery give off the anterior middle cerebral, posterior communicating, and anterior choroid; that of the latter the inferior cerebellar, while the basilar branch of the vertebrals gives off the transverse, anterior cerebellar, superior cerebellar, and posterior cerebral arteries.

The cerebral arteries, anterior, middle, and posterior, are the three largest and most important.

From the circle of Willis and the beginnings of these arteries, several groups of vessels, six in all, are given off. They enter the base of the brain and supply the ganglia and adjacent white matter. They are called the central arteries, and they are the vessels usually affected in cerebral hemorrhages of adult life. They do not anastomose

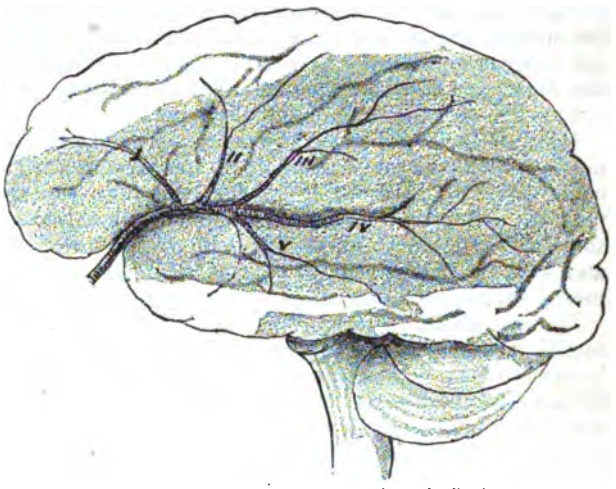

FIG. 4.—Sylvian Artery and Its Cortical Distribution.

with each other or with the cortical arteries. The cortical arteries anterior, middle, and posterior anastomose with each other but slightly. They are distributed very widely and carry much more blood than the central groups. Their distribution is shown in Fig. 3.[1]

The cortical arteries are distributed in the pia, and

[1] Nearly all systematic writers on cerebral anatomy seem to accept the investigations of Duret and Heubner regarding the vascular supply of the cortex as sufficient and complete.

from there they pass in two sets, a superficial and a deep, into the gray matter, and for a short distance into the white matter. They pass straight in at right angles to the surface. They have richly arborescent branches which do not anastomose; consequently, a knife plunged straight into the brain does not cut many vessels.

The blood of the convex and mesial cerebral surface, flowing up from the base, leaves the capillaries and enters veins. Thence it still passes upward, and for the most part enters the longitudinal sinus. The most of the vessels enter the posterior portion of the sinus and in a direction forward and upward, *i.e.*, against the current in the sinus.

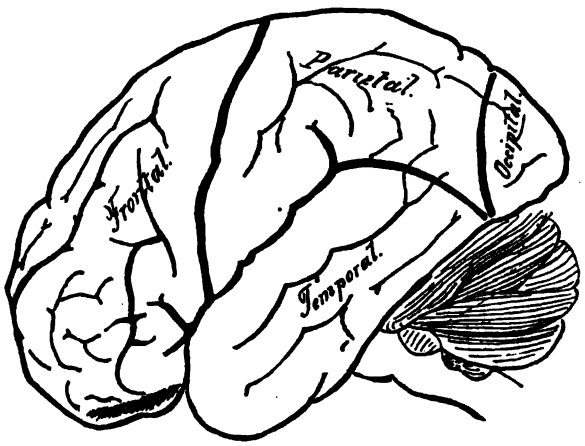

FIG. 5.—Lobes of the Cerebrum.

The course of the blood-current is, therefore, opposed both to gravitation and to the venous flow.

The veins of the cerebrum are: 1, the superficial cerebral; 2, the deep cerebral veins; and 3, the cerebral sinuses.

The superficial cerebral veins are venæ comites. Those on the convex and mesial surfaces empty chiefly into the superior longitudinal sinus, as described; those on the basal surface empty into the cavernous and lateral sinuses. These veins have no valves, and their walls are very thin and without muscular fibres. The deep cerebral veins, or venæ Galeni, receive the blood from the lateral ventricles and from some of the central arteries supplying the basal ganglia. They empty into the straight sinus.

The cerebral sinuses are fifteen in number. The important ones are the superior and inferior longitudinal, the straight, the lateral, the occipital, the cavernous, and the superior and inferior petrosal. They carry blood for the most part in a direction from before backward, and convey it eventually to the internal jugular.

Most of the blood of the convexity and mesial surface must pass into the longitudinal sinus, but there is a slight connection of some of the veins with the superior petrosal and straight sinuses. The superior longitudinal sinus also communicates slightly with veins of the scalp and with the facial vein. Some of the blood from the mesial surface also goes to the veins of Galen.

On the whole, however, the system of the convex and mesial cerebral surface is a close corporation, the blood having to pass into the superior longitudinal sinus and torcular Herophili, where it meets that of the straight and occipital sinuses, and flows forward through the lateral sinuses to the internal jugular. The circulation of the basal surface is less isolated. All the basal sinuses communicate with each other freely, and there are slight communications between the veins of the scalp and the cavernous, lateral, and inferior petrosal sinuses. *It would be safe, perhaps, to tie any of the sinuses*, except the lateral and the posterior part of the longitudinal.

None of the cerebral veins or sinuses have valves. The pressure in the internal carotid arteries is about 150 mm., that in the cerebral sinuses 70 to 80 mm. (Gerhardt), and that in the jugular veins is almost negative. Both arteries and veins are more delicate than the extracerebral vessels. The cerebellar veins, superior, inferior, and lateral, empty into the straight, the lateral, and superior petrosal sinuses.

Except its gray matter, the brain is not a very vascular organ, but this gray tissue ranks in richness of blood-supply with the lungs and liver. The amount of blood in the brain at any one time is only about one to two per cent. of the total blood in the circulation, or about four ounces (Ranke).

The diameter of the common carotids is 6.7 mm. (Thorne), that of the subclavians 6.2 mm., that of the internal carotids 4 mm., and that of the vertebrals 3.5 mm. (Gerhardt). The blood to the brain, therefore, has passages three-fifths as great as the total arterial area near the heart, and the blood enters these passages at a pressure (250 to 150) three-fifths as great as that in the vessels near the heart. In reality, therefore, the brain must get about three-eighths of the blood of the systemic circulation in a given period of time. The cerebral circulation is, therefore, a very rapid one.

It is sometimes important to estimate whether there is cerebral œdema or excessive serous effusion in the cranial cavities. Therefore it may be borne in mind that the cerebro-spinal fluid ranges in amount from two to five ounces. (Luschka, Cotiqua). In old age, it may reach the amount of eight ounces.

The lobes, fissures and convolutions of the brain.—For the purpose of completeness and convenience I give below a very brief enumeration and description of the lobes, primary fissures, and secondary fissures, or sulci, of the brain. The term fissure is sometimes reserved for the seven chief or primary clefts of the brain. The secondary fissures are called sulci.

Our present knowledge of this subject is the result of labors extending over half a century. The progress of its development has three periods, the empirical, the developmental, and the comparative anatomical. To the first belong the studies of Gall, Spurzheim, Burdach, Rolando, Arnold, Cruveilhier, Leuret, Valentin, Foville, and Huschka. But little satisfactory progress was made, however, until attention was turned to the study of fœtal and infants' brains, by Tiedemann and Reichert. Finally, our knowledge was completed by the comparative anatomical studies of Gratiolet, R. Wagner, Huxley, Marshall, Rollerton, Flower, Turner, Ecker, Wernicke, and others.

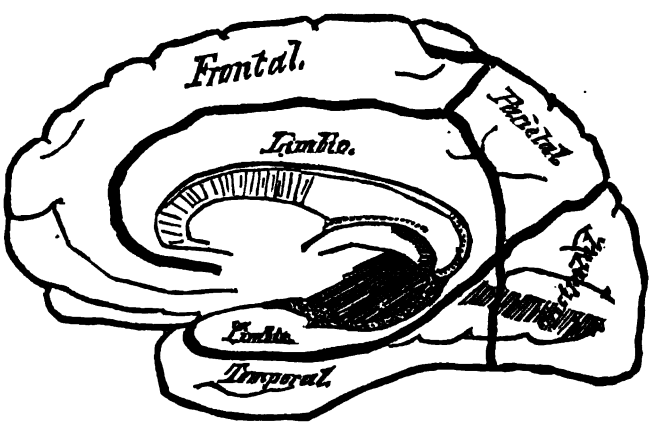

FIG. 6.

The primary or chief fissures of the brain are:

I. The longitudinal.
II. The transverse or choroidal.
III. The fissure of Rolando.
IV. The fissure of Sylvius
V. The parieto-occipital.
VI. The calcarine.
VII. The Bogen fissure, comprising the sulcus corporis collosi, and the sulcus hippocampus.

The secondary fissures, or sulci, will be enumerated in describing the lobes. These are divided into the typical or more or less constant, and the atypical or tertiary fissures.

The primary fissures divide the cerebrum into the following lobes:

I. Frontal.
II. Parietal.
III. Temporal.
IV. Occipital.
V. The central, or island of Reil.
VI. The gyrus fornicatus or limbic lobe.
VII. The olfactory.

The frontal lobe is limited behind by the fissure of Rolando, and on the median surface by the calloso-marginal fissure and its ascending branch. It has the following sulci: 1. Superior frontal and superior precentral. 2. Inferior frontal and inferior precentral. 3. Olfactory. 4. Tri-radiate.

These sulci form the following convolutions: 1. Anterior central or precentral, or ascending frontal, having on its median surface (a) the paracentral lobule. 2. First or superior frontal. 3. Second, or middle frontal. 4. Third, or inferior frontal. 5. The opercular gyrus or operculum at the foot of the fissure of Rolando. 6. The triangular, between the two anterior branches, if they exist, of the Sylvian fissure.

The parietal lobe is limited behind by the parieto-occipital and anterior-occipital fissures, below on its outer surface by the Sylvian fissure and a line drawn back from its upper end to the lower part of the anterior occipital. In front it is limited by the fissure of Rolando. On its median surface it is limited in front by the ascending branch of the calloso-marginal fissure, behind by the parieto-occipital, and below by the subparietal fissure.

Its important sulci are: 1. The parietal or interparietal. 2. The post-central.

The convolutions formed are, on the convex surface: 1. The post-central, or ascending parietal. 2. The superior parietal lobule, having on its median surface (a) the quadrate lobule or præcuneus. 3. The inferior parietal lobule, which is composed of (a) the supra-marginal gyrus, (b) the angular gyrus.

These are variously described, but are best considered as the one (a), the supra-marginal, surrounding the posterior end of the fissure of Sylvius, the other (b), the angular, as beginning at the upper limit of the first temporal fissure and extending back as far as the anterior occipital fissure.

The occipital lobe.—This is limited on its convex or lateral surface, anteriorly, by the parieto-occipital fissure, below this by the anterior occipital fissure and inferior occipital fissure. These in apes form a single continuous fissure sharply separating the occipital from the other lobes. On its median surface the parieto-occipital fissure limits it in front. On the under surface the anterior edge of the tentorium about marks the anterior limit of the lobe.

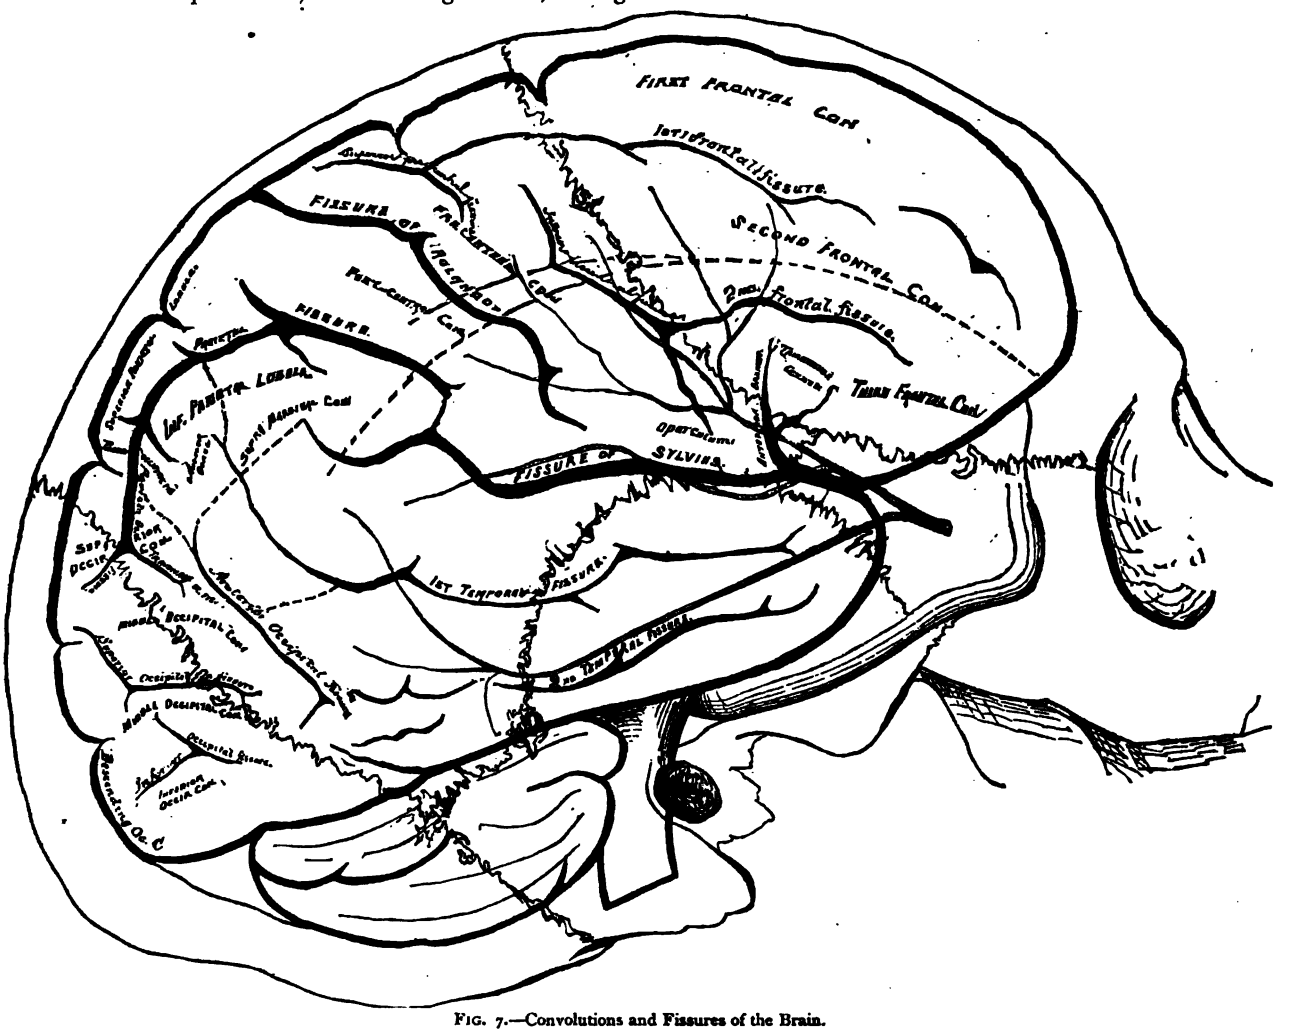

FIG. 7.—Convolutions and Fissures of the Brain.

The sulci are: 1. The transverse occipital (ape fissure of some writers). 2. The superior occipital. 3. The inferior occipital. On the median surface: 4. The calcarine, which joins the parieto-occipital. 5. The inferior occipito-temporal or fourth temporal.

The convolutions on the convex surface are: 1. The superior occipital. 2. The middle occipital. 3. The inferior occipital. 4. The descending occipital. On the median surface we find: 5. The cuneus. 6. Descending occipital.

The temporal lobe.—The convex or lateral surface shows the following sulci: 1. The first temporal or parallel sulcus. 2. The second or middle sulcus. On the under and median surfaces are: 3. The third or inferior temporal sulcus. 4. The fourth temporal or inferior occipito-temporal or collateral sulcus, which extends into the occipital lobe. 5. The hippocampal sulcus, which really belongs to the limbic lobe.

The convolutions are: 1. The first temporal convolu-

tion. 2. The second temporal convolution. 3. The third temporal convolution. 4. The lateral occipito-temporal, oral fusiform convolution. 5. The median occipito-temporal or lingual convolution. 6. The hippocampus convolution. 7. The uncinate convolution.

The island of Reil, or intermediate lobe (lobus centralis, lobus caudicis).—This has a circular sulcus surrounding it, and several more or less short vertical sulci dividing it into from five to seven short gyri.

The gyrus fornicatus or limbic lobe is made to include the gyrus fornicatus proper, or gyrus cinguli, the isthmus, the hippocampal gyrus, the uncinate and the dentate gyri.

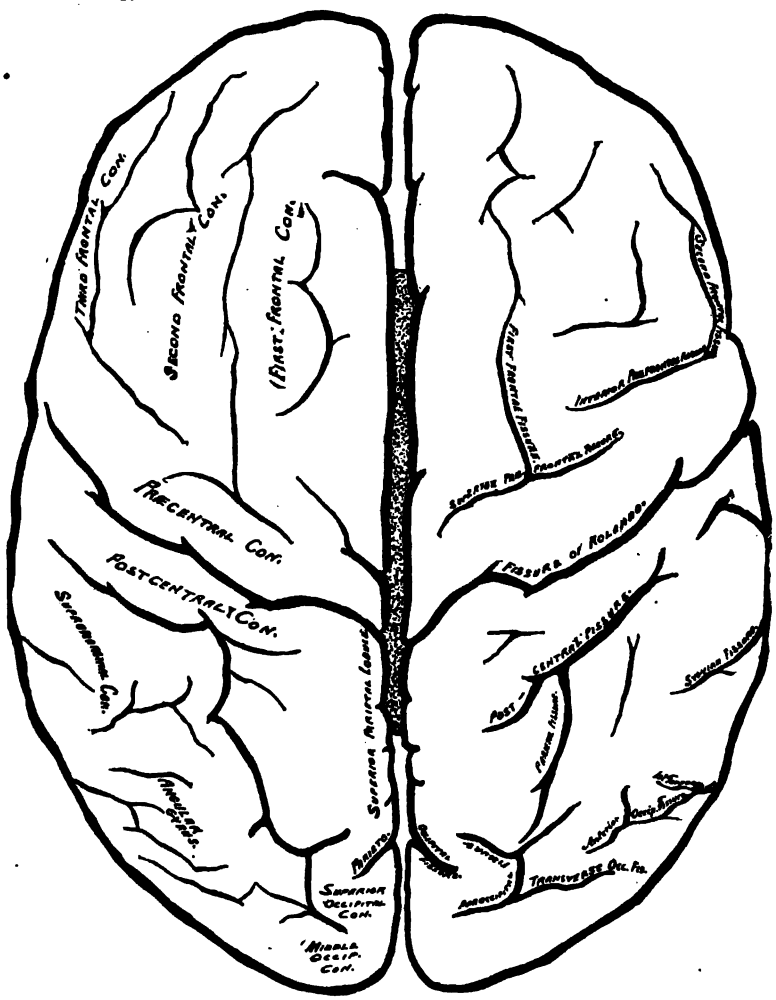

FIG. 8.—Convolutions and Fissures, Vertical Aspect.

The olfactory lobe.—The positions of these various lobes and gyri are shown on the accompanying diagrams, Figs. 5, 6, 7, 8, 9.

These diagrams are based on drawings made by myself of the fissures in the occipital and temporal regions of twenty cerebral hemispheres; on the photographs of brains in Dalton's work, together with a study of Ecker's and Wernicke's, and Wilder's descriptions. They differ from the regular Ecker diagrams in representing the parоccipital fissure as generally independent of the interparietal (I have never found them freely continuous), and in representing the anterior occipital fissure as described by Wernicke. This latter fissure is not always present, or at least easily made out; but it is to be found in the majority of brains, and often very typically. A shallow sulcus almost always connects it with the first temporal sulcus.

CRANIO-CEREBRAL TOPOGRAPHY. HISTORICAL.—Gratiolet,[1] in 1857, first undertook to examine into the relations of the cranial surface to the cerebral convolutions beneath. It led him to his classification of human races into the frontal, the parietal, and the occipital, but his observations upon the positions of the fissures were incorrect, and need not be referred to further.

In 1861, and again in 1877–78, Broca[2] made some further researches (Fig. 10). In 1868, Bischoff[3] contributed to the same subject. In 1872, Heftler[4] continued the work in a much more elaborate fashion (Fig. 11). A little later Turner,[4] of Edinburgh, published his contributions.

In 1875, Féré[5] contributed a most valuable and practical paper, giving results which we still use.

Fouillehouze[6] made some special studies of cranial topography in children and adults (Fig. 12).

Ecker,[7] in 1876, wrote a monograph upon this subject.

Lucas-Championnière,[8] in 1878, devised a scheme for locating the region of the cerebral fissures upon the cranium.

Pozzi, working under Broca, made some original observations in 1877 (*Archives générales de Médecine*, 1877, vol. i.). English and American surgeons and neurologists have generally accepted a method elaborated by Dr. Robert W. Reid.[9]

Mr. Victor Horsley[10] has described in a very careful manner the plan which he uses in determining the topography of the cranium. He has especially shown the value of using the skull landmarks and relative measurements.

Professor Thane,[11] of University College, London, has determined a rule, which is a very exact one, for locating the upper end of the fissure of Rolando.

Dr. Arthur W. Hare has modified Thane's rule by showing that the distance from the glabella to the upper end of the fissure of Rolando is 0.557 of the entire distance from the glabella to the inion. He has also shown that the fissure in question makes an angle of 67° with the longitudinal fissure.

OBSERVATIONS ON CRANIO-CEREBRAL TOPOGRAPHY IN CHILDREN.—I have examined the cranio-cerebral relations in five infants, ranging in age from one to eighteen months.

The landmarks were marked out, and the theoretical position of the fissures drawn upon the scalp. A hole was made directly into the brain at the various points whose relations were to be established, and a staining fluid injected. Half the skull cap was then removed, the points of injection studied in reference to the convolutions, and measurements taken of variations from the theoretical points.

The bregma was found by prolonging the lines of the coronal sutures until they met in the median line. It naturally lies close to the posterior edge of the anterior fontanelle.

My observations show that in children's brains:

1. The upper end of the fissure of Rolando is usually just at the theoretical point, but may be 1 to 2 ctm. in front of it. It was 30 ctm. behind the bregma in one case, 38 and 40 in two others. The lower end is just touched

by the stephanion-asterion line, as described later. It often runs nearly into the fissure of Sylvius. The direction is perhaps a little more vertical than in adults.

2. The fissure of Sylvius has its point of division a little higher than in adults. Its posterior branch lies either just under the squamous suture at its highest point (in two oldest cases), or above it ½ to 1 ctm. (3 cases). It runs up to and usually above and in front of the parietal boss, *i.e.*, the parietal boss is relatively lower than in adults.

The length of the vertical branch is 1.5 to 2 ctm. Its direction up and slightly forward.

3. The parieto-occipital fissure is either exactly under the lambda (2 cases), or 1 to 2 ctm. in front of it (3 cases).

4. The transverse fissure was directly under the inion, hence the relations of the cerebellum are the same as in adults.

The two central convolutions together had an average width of 2.5 ctm. The precentral fissures were just posterior to the coronal suture, as in adults. The second frontal lay nearly under the frontal ridge. My measurements gave a larger naso-bregmatic arc than is usually given (see Table), and show the frontal lobes to be relatively large.

	Age.	Antero-post. diam.	Bi-par. diam.	Naso-occip. arc.	Naso-bregm. arc.	Naso-lamb. arc.	Greatest circumference.

TOPOGRAPHICAL RELATIONS OF CRANIUM AND CONVOLUTIONS.—For surgical purposes it is important to map out: The fissure of Rolando; the fissure of Sylvius; the parieto-occipital fissure; the transverse fissure, or rather the boundary between occipital lobe and the cerebellum; the precentral sulci; the inter-parietal fissure; the post-central sulci; the first and second temporal sulci.

The general principle which I have tried to follow in making out the rules for determining the cranio-cerebral relations is that of taking certain landmarks on the skull and determining the location of subjacent fissures by establishing their relation to these landmarks. The only fault to be found with the careful work of Heftler, Broca, Féré, Reid, and others, is that they used definite measurements from given points. This is shown to be incorrect by the wide range of distances given—as for example, the upper end of the fissure of Rolando ranges from 40 to even 60 ctm. behind the bregma. On the other hand, the *relative method* of finding this fissure, as given by Hare, is almost absolutely accurate for adult skulls of all normal sizes or shapes.

It is to-day an undisputed fact that every part of the cranial surface corresponds to a definite part of the cerebral surface. A high grade of atypical diminution in a certain part of the skull means that there is a corresponding aplasia of the brain below (Benedict).

While claiming for the relative method the merit of being more accurate and scientific, I do not deny that the absolute and numerical methods of Reid and Féré are not sufficiently accurate for most purposes. But as our knowledge of cerebral localization widens, we find it increasingly important to be able to map out smaller areas, and with the greatest certainty possible.

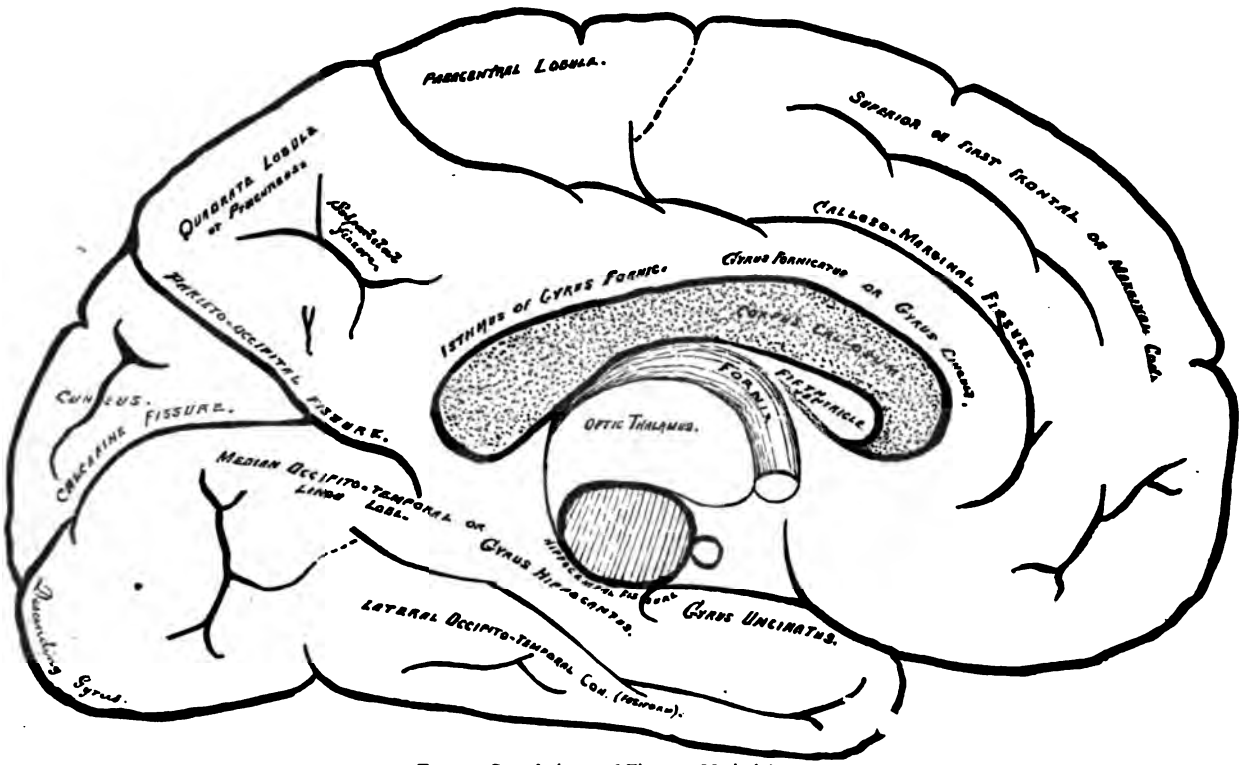

FIG. 9.—Convolutions and Fissures, Mesical Aspect.

The methods given below I have arranged in the form of rules. The rule gives the general and best guide in ordinary cases. If necessary, it may be supplemented or corroborated by applying other and numeral tests, as given by various investigators of the subject.

In the rules, it will be seen that that given for the fissure of Rolando is based upon the observations of Thane, Hare, and Horsley, with the addition of lines for determining the lower end of the fissure, which I have formulated from studies on skulls and tested upon the cadaver.

The various descriptions for finding the fissure of Sylvius are most discrepant; applying them upon a skull one gets several different points included in an area about an inch in diameter. Obviously, all are not accurate. I believe that the one which I have adopted, which is in the main like that of Horsley, is the safest.

Instruments of precision to aid in determining the location of the cerebral fissures have been devised by Broca, Lucas-Championnière, and others.

Broca devised a simple instrument which he called an "équerre" or square, to be used for determining the position of the auriculo-bregmatic line. It was simply a T-shaped arrangement of steel ribbons. At the junction of the two pieces was fastened a short wooden plug. The instrument was arranged so that the plug entered the external auditory meatus, and the anterior limb of the cross-

piece passed round just under the nostrils. The straight piece then passed over the head and just in front of the bregma (Lucas-Championnière) (see Fig. 13). M. L. Championnière cut out a square piece of cardboard so that it would fit over the head, each side passing over the auditory meatus. A straight piece of wood or a pencil is thrust through one side at exactly right angles to the plane of the cardboard. When the cardboard is arranged so that the pencil is on an exact level, the plane of the board passes through the bregma and is identical with the auriculo-bregmatic line (see Fig. 14).

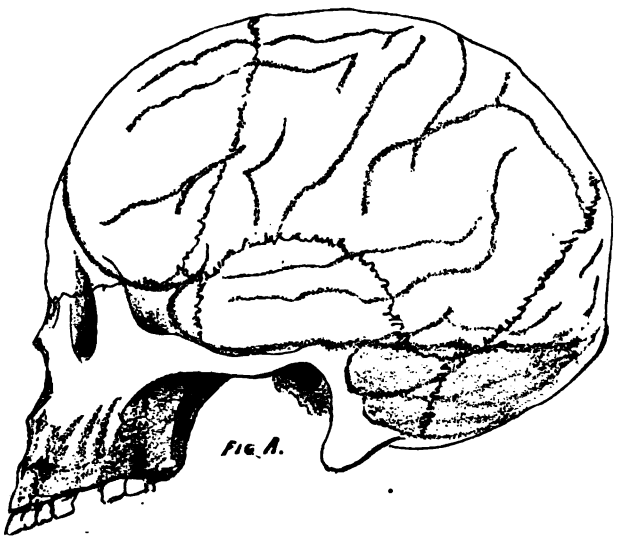

FIG. 10.—Broca's Diagram of Cranio-cerebral Relations in a Negro.

It is evident that such instruments are unnecessary when, as is almost always the case, the bregma can be felt with the finger.

Mr. Horsley devised an instrument of soft iron nickelized, ten inches long and one centimetre broad, from the middle of which branches off another strip one centimetre broad, the two making an angle of sixty-seven degrees. On the short arm is marked on both sides a scale of inches commencing half an inch from the middle line. The instrument is used thus: The long arm is laid on the middle line of the head, which has been previously marked; the angle between the arms is made to coincide with the theoretical situation (Thane) of the upper end of the fissure of Rolando; a line drawn down the anterior border of the short arm for a little over two inches gives the course of the upper two-thirds of the fissure of Rolando.

Mr. Hare ("Intra-cranial Tumors," loc. cit.) describes an instrument which he calls Wilson's cyrtometer, and which allows one to apply still more readily his relative method for finding the position of the fissure of Rolando.

It consists of three strips of nickel-plated soft iron, with a tape or clamp for securing them in position. The broadest, transverse strip is applied circumferentially around the head, embracing the glabella, external angular process, and external occipital protuberance, and is firmly secured in place. A narrower longitudinal strip of metal, attached to the first strip at right angles, passes backward in the middle line over the scalp to the occipital protuberance. This strip is marked with two series of letters, capitals near the occipital end, small letters about the middle of the strip. These two series of letters are related to one another, each to each as 0.557 is to unity measured from the frontal end of the strip. Hence, when any given capital letter falls on the occipital protuberance, the corresponding small letter points out the upper limit of the fissure of Rolando. A third narrow reversible strip glides forward or backward on the longitudinal strip, and marks an angle of sixty-seven degrees opening forward, thus giving the course of the fissure.

Instead of using letters, I have had an instrument made on which various distances, measured from the frontal end of the longitudinal strip, have been marked. These distances range from 28 to 38 ctm., the ordinary range of the naso-occipital arc. In the middle of the strip the same figures are marked, each one representing 0.557 of the naso-occipital measurement.

In addition, I have had added a clip of steel which slips along the under edge of the broad or horizontal strip. To the lower edge of this is pivoted a narrow strip of metal. The clip is placed so that the frontal end of the movable strip lies over the external angular process. The strip is then fastened upon the scalp so that its lower edge just passes through the squamous suture. A line drawn along the upper edge shows the position of the horizontal part of the fissure of Sylvius.

The instruments of precision described are convenient, but nothing more than two strips placed at an angle of sixty-seven degrees is absolutely necessary.

RULES OF CRANIO-CEREBRAL TOPOGRAPHY.—*Rule* I. *The longitudinal fissure.*—This corresponds with the naso-occipital arc.

Rule II. *The fissure of Rolando:* (*a*) The upper end. Use the cyrtometer as directed, or measure the distance from the glabella to the inion. Find 55.7 per cent. of this distance, and the figures obtained will indicate the distance of the upper end of the fissure of Rolando from the glabella. As the naso-occipital arc ranges from 28 to 38 ctm. (11 to 15 inches), the point sought for lies from 15.7 to 26.8 ctm. from the glabella.

(*b*) The course of the fissure. Starting from the upper end of the fissure, lay off with the cyrtometer a line forming an angle of sixty-seven degrees anteriorly with the longitudinal fissure. This gives the direction of the upper two-thirds of the fissure, or for about 5.6 ctm. (2¼ inches). The lower third, about 2.1 ctm., is slightly more vertical. The bend of the fissure is about on a level with the anterior end of the parietal fissure. The total length of the fissure averages 8.5 ctm. (3⅜ inches).

(*c*) To find the lower end more exactly, if needed: Lay off a line from the stephanion to the asterion, and another from the bregma to the external auditory meatus. The point of intersection will be just over the lower end of the fissure. It should be about 1 ctm. above the fissure of Sylvius. The asterion is usually easily felt just behind the upper part of the mastoid process.

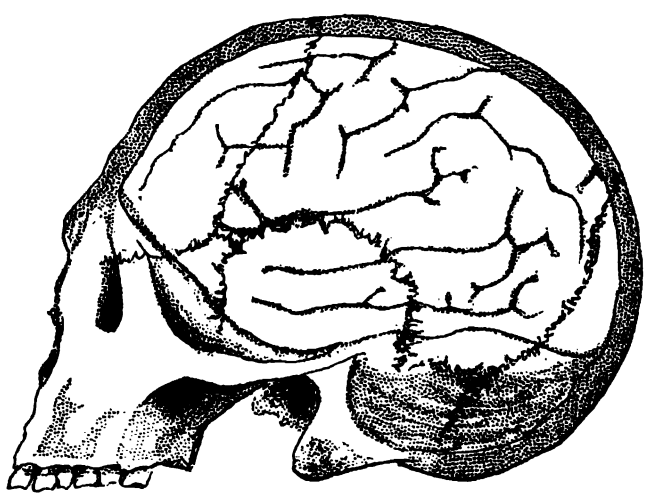

FIG. 11.—Heftler's Diagram of Cranio-cerebral Relations.

Supplementary.—The upper end of the fissure is 48 mm. back of bregma in men; 45 mm. in women (Broca, Féré). In French skulls Lucas-Championnière makes it 55 mm. It is about two inches (50 mm.) behind the bregma (Turner) in Scotch skulls. It is 48 mm. behind the bregma (Heftler) in Russian skulls. It is 38 mm. behind the bregma in adult men (Ecker) German skulls. The range is thus from 38 to 55 mm., or about 20 mm. The lower end is 28 mm. behind the coronal suture (Heftler, Russian skulls); it is 17 mm. in German skulls (Ecker). It is 25–30 mm. in French skulls (Fouillehouze, Féré, and Broca), where it

reaches to within 1 ctm. of the fissure of Sylvius. The range is therefore from 25 to 30 mm.

Physiological variations.—In imbeciles with arrested development of the fore brain the upper end is nearer the bregma, being from 30 to 32 ctm. behind it (Féré). The lower end is not changed. In persons with persistence of the medio-frontal suture, the growth of the posterior lobes pushes the fissure forward.

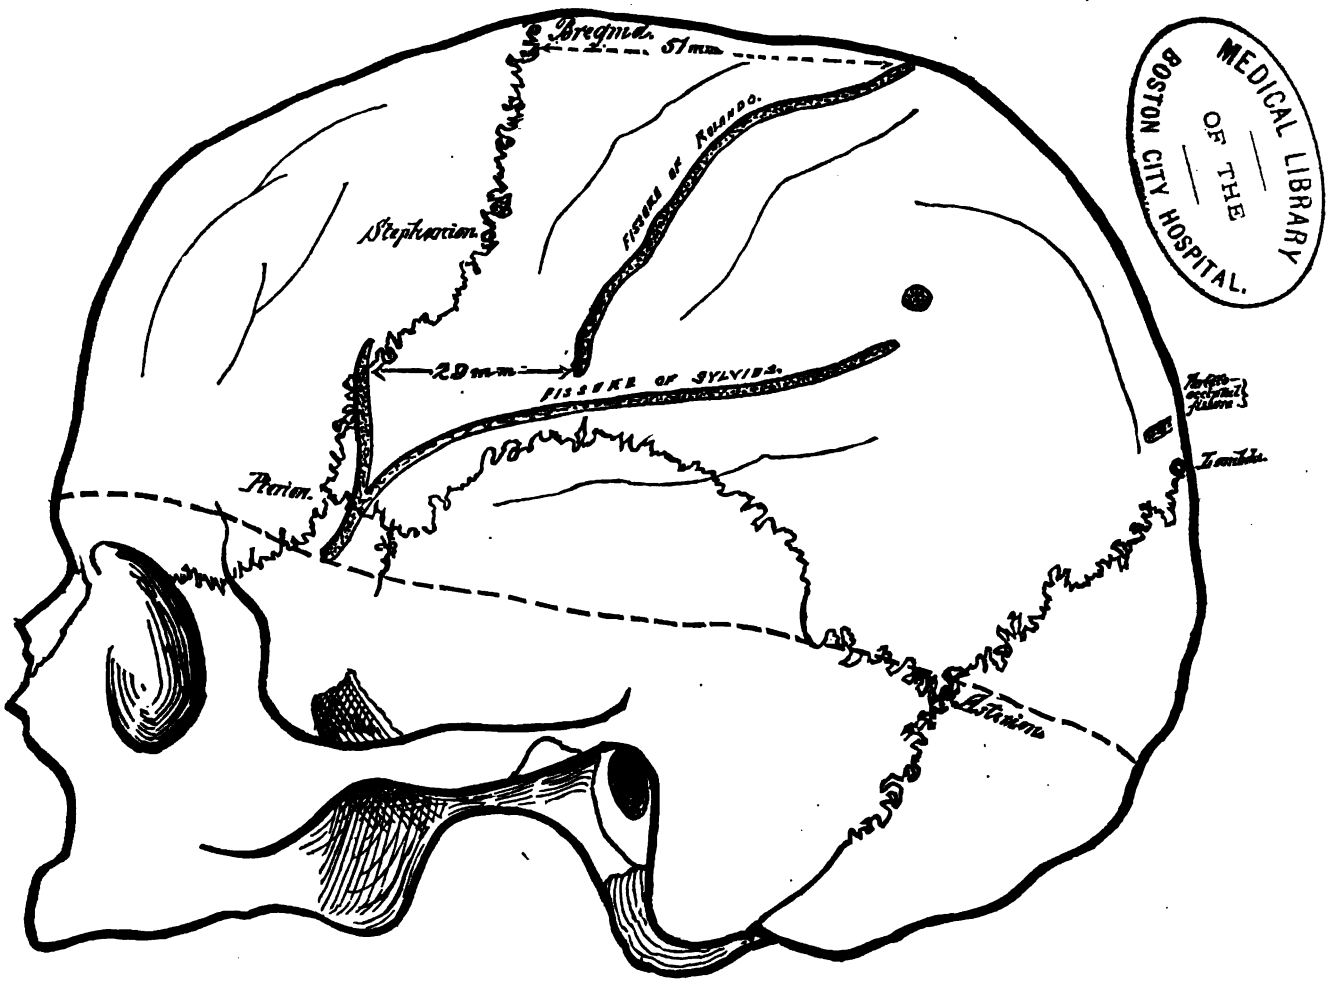
In children.—The (Fouillehouze) upper end of the fissure is in the first months of life from 30 to 35 ctm. behind the bregma, the antero-posterior diameter of the brain being 113.50 mm. At the second and third year of life it is 42.33 behind the bregma, and after this it rapidly assumes the same relations as in the adult. The lower end of the fissure is higher proportionately up to the third year, then it falls to the adult relations.

It will thus be seen that the fissure of Rolando is further back and higher up proportionately in children (see Fig. 16).

This corresponds with my measurements (*vide ante*), except that in some cases with a short naso-bregmatic arc the fissure is a little in front of the theoretical position. As a rule, in children the surgeon will find the upper end of the fissure of Rolando either at or a little in front of the theoretical position.

Rule III. *To find the fissure of Sylvius.*—Draw a vertical line from the stephanion to the middle of the zygoma. Draw a horizontal line from the external angular process to the highest part of the squamous suture; continue this back, gradually curving it up till it reaches the parietal eminence. The junction of the two lines will be at the beginning of the fissure of Sylvius. The vertical line indicates nearly the position of the anterior or vertical branch of the fissure, which is, however, directed a little more forward, and is about 2.5 ctm. (1 inch) in length. The posterior part of the line indicates the position of the posterior branch of the fissure. The triangular gyrus and motor speech centre lies just anterior to the vertical branch of the fissure. The operculum lies just back of it. The tip of the temporal lobe reaches nearly as far forward as the posterior edge of the orbital process of the malar bone. The fissure of Sylvius is separated from the lower end of the precentral sulcus by a convolution one ctm. wide on the average (Horsley).[1]

Supplementary.—Reid's method of finding the fissure of Sylvius is to "draw a line from a point 1¼ inch behind the external angular process to a point ¾ inch below the parietal eminence. The ascending branch starts from a point ¾ inch back from the anterior end of this line, and 2 inches (5 ctm.) back of the external angular process.



MEDICAL LIBRARY OF THE BOSTON CITY HOSPITAL.

FIG. 12.—Fouillehouze's Diagram of Cranio-cerebral Relations in Adult.

Dr. Hare draws a line from the external orbital process to the inion. A line from a point 1⅛ inch behind the anterior end of this line is taken, and a straight line from here to the parietal eminence marks the course of the posterior or main branch of the fissure of Sylvius.

Pozzi describes the fissure as beginning 5 mm. behind the anterior point of the pterion and passing just above the parieto-squamous suture.

Fouillehouze gives the same relations as Pozzi.

Turner found that the fissure began behind the posterior border of the lesser wing of the sphenoid.

[1] The above rules correspond to the anatomical fact upon which all observers agree, that the division of the fissure of Sylvius lies under the pterion. In twelve skulls upon which I have determined these lines the horizontal line passed through the external angular process, posterior point of pterion, and parieto-squamous suture and lambda in every case. The vertical line is not so constant, but in nine out of twelve cases it passed through the pterion; in the remaining three cases it fell just behind the pterion, but in these cases also, the pterion was further forward than in the average of cases. So that the vertical line, as Mr. Horsley points out, is a safe guide. The average distance of the posterior point of the pterion from the summit of the external angular process, I found to be about 4.5 ctm., ranging from 3 to 5.8 ctm. The distance is, however, quite a constant one.

Féré describes the fissure as beginning 22 to 25 mm. in front of the auriculo-bregmatic line, on a horizontal plane going through the external orbital process, parallel to the alveolo-condyloid plane.

Heftler describes the fissure of Sylvius as dividing 13 mm. behind the coronal suture, and just under the posterior point of the pterion (see Heftler's Fig.)

Horsley, as I understand his description, finds the beginning of the fissure at the pterion, and the pterion is

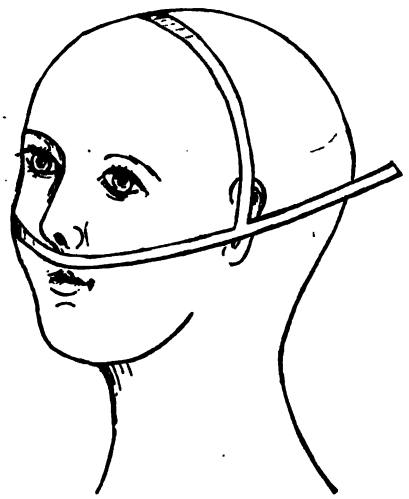


FIG. 13.—Broca's *Equerre.*

found by dropping a vertical from the stephanion to the middle of the zygoma. The pterion is just above the middle point of this line. I do not find the pterion always at this point, but it does mark the point of division of the fissure pretty accurately, and hence this line is adopted in my rule.

Broca describes the fissure as running just below the squamous suture. But most authorities agree that it lies under or just above it (1 mm., Horsley).[1]

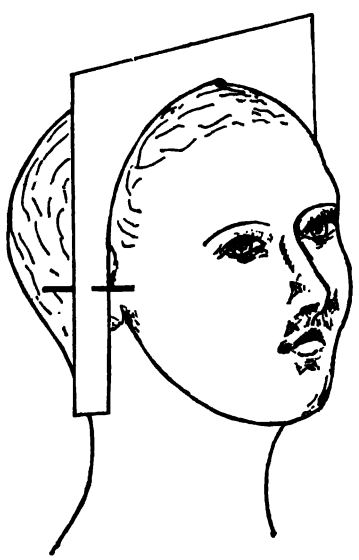

FIG. 14.—Lucas-Championnière's Instrument for Determining Bregma, etc.

Physiological variations.—In children, up to the third or fourth year, the fissure is more oblique and lies further above the squamous suture, an average of 12 mm., viz., 8 to 17 mm. (Fouillehouze) (see Fig. 13).

I have not found the variations so marked. In some young children the fissure lies just under the squamous suture as in adults; usually it is a little above it.

Rule IV. *To fina the parieto-occipital fissure.*—Find the lambda, mark a point 3 mm. anterior to it, draw a line through this at right angles to the longitudinal fissure, extending about 2.25 ctm. (1 inch) on each side of the median line. If the lambda cannot be felt, its position may be found by measuring the naso-occipital arc, and taking 22.8 per cent. of it. This indicates the distance of the lambda from the inion or external occipital protuberance.[1] The average distance in male adults is 7.42 ctm. It is greater in women, by a little over a millimetre, than in men.

Supplementary.—The position of the parieto-occipital fissure is subject to considerable variations. Heftler found it just at the lambda on the average. Ecker figures it several millimetres anterior to the lambda. Fouillehouze places it from 5 to 21 mm. in front of the lambda. Féré found the fissure under the lambda in 39 out of 62 cases, and from 1 to 4 mm. above in 24 cases (mostly old women). Turner thought the fissure always in front of the lambda for from 0.7 to 0.8 inch. Broca asserts that it may be from 1 to 4 mm. in front or behind it; on an average it is just beneath it. Reid finds the fissure by con-

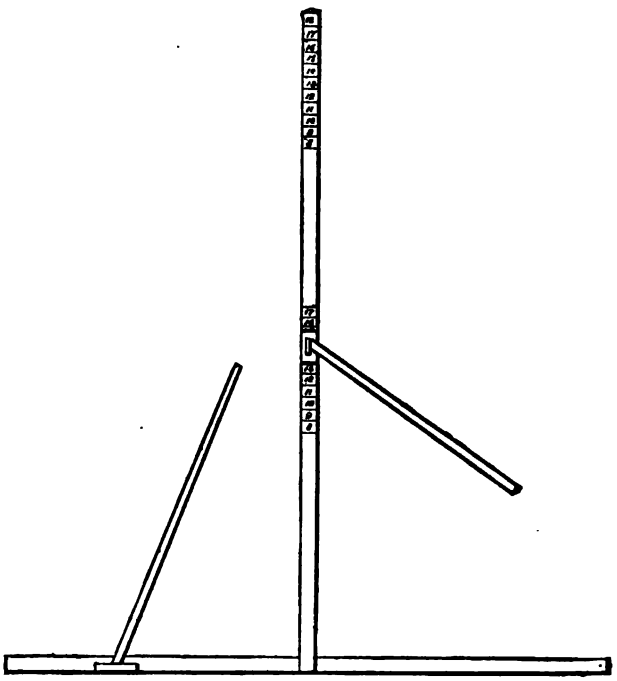

FIG. 15.—The Cyrtometer.

tinuing a line from a point 1¼ inch behind the external angular process of the frontal bone to a point ¾ of an inch below the most prominent part of the parietal eminence. This places the fissure considerably in front of the lambda. Horsley states that the fissure is usually 2 or 3 mm. in front of the lambda. Hare states that the fissure is two inches behind the upper end of the fissure of Rolando, and from ¼ to ½ inch above the lambda.

Physiological variations.—In children, up to the third year, according to Fouillehouze, the fissure is from 5 to 21 or 31 mm. in front of the lambda. I have found it from 15 to 20 mm. in front usually, but it may be directly under it even in small infants. The general results of observations are, therefore, that the parieto-occipital fissure lies a little in front of the lambda in adults; rather further in front proportionately in young children.

Rule VI. *To find the interparietal sulcus.*—First mark out the lines for the fissure of Rolando, fissure of Sylvius, and parieto-occipital fissure, and mark the position of the parietal eminence. Find a point on a level with the bend of the fissure of Rolando, and about 2 ctm. behind it. From this draw a curved line up and back, keeping it half-way between the fissure of Rolando and parietal eminence as it ascends, and half-way between the parietal eminence and longitudinal fissure as it passes back. Continue the line back till it reaches a point just outside the external end of the parieto-occipital fissure. This fissure

[1] The diagrams given by Broca, Heftler, and Fouillehouze, to show the relations of the cranial to the cerebral surfaces, are shown in Figs. 10, 11, 12.

[1] From calculations based on Benedict's measurements of skulls.

divides the parietal lobe into a superior and inferior lobule. The parietal eminence lies over or a little behind the supra-marginal gyrus, and about over the middle of the inferior parietal lobule.

Supplementary.—Reid places the anterior end of this fissure about one inch above and behind the angle formed by the fissures of Rolando and Sylvius. As the fissure is continued up, it is at first about ⅜ of an inch behind the fissure of Rolando. The posterior part lies about ½ inch outside the parieto-occipital fissure. Heftler states that the interparietal fissure begins 15 to 20 mm. behind the fissure of Rolando. This fissure is very variable and irregular in its course. Hare states that the parietal fissure begins opposite the middle third of the fissure of Rolando and one inch behind it. It ascends for about an inch, and then turns back toward the outer end of the parieto-occipital.

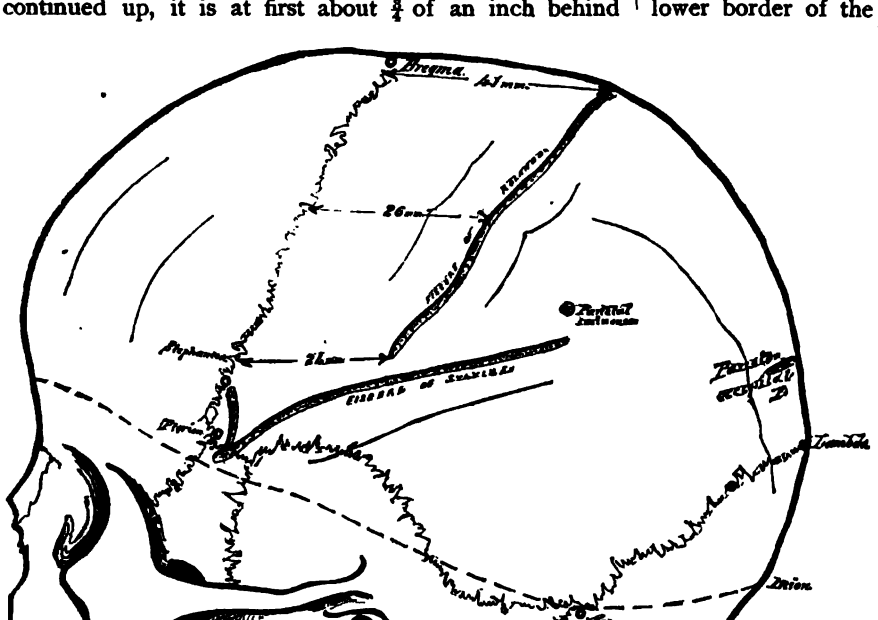

FIG. 16.—Fouillehouze's Diagram of the Cranio-cerebral Relations in Children.

Rule VII. *To find the inferior precentral or vertical sulcus, and the inferior frontal and superior frontal sulci.*—The inferior precentral or vertical sulcus passes nearly vertically just posterior to the coronal suture. Its lower end is 1 ctm. above the Sylvian fissure (Horsley), and 2 mm. behind the coronal suture. Its upper end reaches to the level of the mid-point of the fissure of Rolando, and is 4 mm. behind the coronal suture. It lies 2 to 2.5 ctm. anterior to the fissure of Rolando.

The inferior, or second, frontal sulcus passes forward from the precentral sulcus at a point a little above the stephanion. It continues forward in a line nearly identical with the frontal part of the temporal ridge (Reid).

The superior, or first, frontal sulcus begins at a point half-way between the fissure of Rolando and a line prolonged up from the inferior precentral sulcus (Horsley).

This point should be from 2 to 2.5 ctm. in front of the fissure of Rolando. The fissure passes forward parallel to the longitudinal fissure, and its line, if prolonged, ends in the supra-orbital notch (Reid).

Supplementary.—The frontal convolutions, according to Turner, reach from 1.2 to 1.3 inch behind the coronal suture.

The first frontal convolution passes under the frontal protuberance, according to Pozzi.

The anterior end of the frontal lobes reaches to a point determined by the thickness of the frontal bone. This ranges from 2 to 8 or more mm.

The floor of the anterior fossa reaches in front to a level a little above the supra-orbital margin (16 mm., Heftler). It slopes down and backward, its posterior limit being indicated by the lower end of the coronal suture.

Rule VIII. *To find the temporal lobe and the first and second temporal sulci.*—The temporal lobe is limited above by the fissure of Sylvius, below by the contour line of the lower border of the cerebrum. This corresponds to a line drawn from a point slightly (about 12 mm.) above the zygoma and the external auditory meatus to the asterion, and continued on along the superior occipital curve to the inion. The anterior border of the lobe corresponds to the posterior border of the orbital process of the malar bone. The posterior border of the temporal lobe is somewhat arbitrarily found by drawing a line from the Sylvian fissure line at a point 2.5 ctm. below the parietal eminence, backward and downward to the anterior occipital fissure.

The temporal lobe is about 4 ctm. (1⅝ inch) wide at the external auditory meatus. A trephine, as Bergmann states, placed half an inch above the meatus would enter the lower part of the lobe. The middle of the lobe is in a vertical line from the posterior border of the mastoid process. A line from the upper end of the fissure of Rolando to the point of the process would pass through this important sensory area.

To find the first temporal fissure, draw a line 2.5 ctm. below and parallel to the Sylvian fissure (Reid). The second temporal fissure is about 2 ctm. below the first (Reid).

Rule IX. *To find the occipital lobe and anterior occipital fissure.*—The upper anterior border lies under a line drawn from just above the lambda (1 to 2 mm.), curving out and down to a point about at the junction of the anterior and middle third of the line from the inion to the asterion. The lower border corresponds pretty closely to the superior occipital curved line. The anterior occipital sulcus, when present, should lie in the anterior border of the lobe.

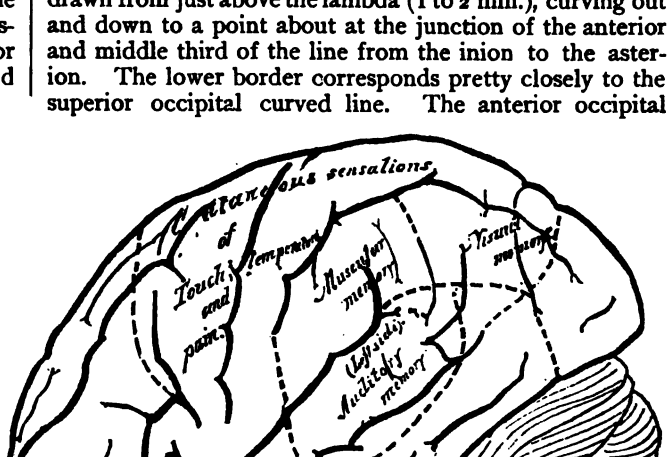

FIG. 17.—Sensory Cortical Localizations.

Rule X. *To find the position of the central ganglia*, viz., corpus striatum and optic thalamus, draw a line from the upper end of the fissure of Rolando to the asterion, practically a vertical line. This limits the optic thalamus posteriorly. A vertical line parallel to the first, a little in front of the beginning of the fissure of Sylvius, limits the corpus striatum anteriorly. A horizontal plane 45 mm.

below the surface of the scalp at the bregma, limits the ganglia superiorly. The ganglia lies about 35 ctm. below the superior convex surface of the brain (Féré).

Rule XI. *To avoid the meningeal arteries and central sinuses.*—The course of the middle meningeal artery has been described and is seen in Fig. 3. This artery is the only one of importance or very definite course. The superior longitudinal sinus generally (not always) lies a little to the left of the median line. The torcular Herophili lies approximately under the inion. The lateral sinus lies generally about under a line from the inion to the asterion, and just grooves the postero-inferior angle of the parietal bone.

FIG. 18.—Diagram Showing Cerebral Fissures and Cortical Centres Mapped out on the Scalp in Accordance with Rules of Cranio-cerebral Topography.

Rule XII. *To outline the base of the brain.*—The rules for this are given in Rules VII., VIII., and IX., for finding the frontal, temporal, and occipital lobes.

LOCALIZATION OF THE CEREBRAL FUNCTIONS.—So much has been written upon this subject recently, that I do not propose to enter upon it now. The articles of Horsley, of Leyden, and Jastrowitz, of Roswell Park, Dr. C. K. Mills, Dr. M. Allen Starr, and Drs. E. C. Seguin and R. F. Weir cover the subject of our knowledge up to the present date. I may be permitted to refer, perhaps, to a contribution made by myself to the localization of the cutaneous sensory functions in the *Journal of Nervous and Mental Diseases* for November, 1888.

In Figs. 17 and 18 will be found representations of the functions of the cortex.

50 WEST FORTY-SIXTH STREET.

THE DANGER OF PRACTISING MEDICINE.—The recent death in Georgia of Dr. J. B. Manson, one of the most eminent, skilful, and benevolent physicians of that State, at the hands of an infuriated father whose child died from typhoid fever while under the care of Dr. Manson, draws attention to one of the many dangers which surround a doctor. Ill-balanced minds under the pressure of great grief often unjustly blame the attending physician for the death of their loved one; but, fortunately, it is rare for the result to be so sad as the one above referred to.—*The Weekly Medical Review.*

LAPAROTOMY AND NEPHRORRHAPHY.

BY JOSEPH D. BRYANT, M.D.,

NEW YORK.

L. H. W——, aged twenty-eight, clerk; single; temperate; family history good. W—— has suffered for a long time from dyspepsia. Had chills and fever some years ago. He left school at eleven years of age and went to hard work. About seven years ago, while at work, felt a peculiar sensation in the right lumbar region attended with fatigue. Had severe constipation and loss of appetite at this time. In the evening of the same day there was noticed marked tenderness at the seat of the pain; felt chilly and suffered from nausea. Pain rapidly became so severe that walking caused great suffering, and patient could not stand erect; it also prevented him from sleeping. These symptoms continued for two days, with diminishing severity. At the end of this time he felt quite well again, and the bowels resumed the normal function. About three months after this time a similar attack occurred, and thereafter, at intervals of one, two, or three months, the attack was repeated. The attacks usually began in the afternoon, and by evening he was obliged to take to bed. The later attacks were attended by severer nausea, by vomiting and retching. The vomited matter was usually of a bitter taste and of a yellowish color. The constipation, too, became more obstinate, and the stools were small in size and quantity. He says they resembled a pencil in shape and size. Mucous discharges from the bowels often attended the attacks. The urinary secretion was usual in all respects, so far as he was able to determine. The attacks at this time varied in length somewhat; they lasted from one day and a night to three or four days and nights continuously, during which time no solid food could be retained by the stomach without severe distress in the right lumbar region. Strong purgatives on these occasions failed to produce the usual effect. During the later attacks he suffered much from distention of the lower portion of the abdomen; the degree of the distention increased with the repetitions of the attacks.

After suffering for a year or so he consulted many physicians and surgeons regarding the nature of his trouble, but was greatly discouraged by the differences of opinions expressed, and by the increase in the frequency and severity of the attacks.

In February, 1887, he consulted Dr. Janeway, who diagnosticated partial obstruction of the colon, complicated with floating kidney of the same side (right).

Some months later he complimented me with a call, having begun again his tireless search for someone who could tell him the cause of his trouble, and would promise him relief At that time he had a tender, somewhat painful movable tumor in the right lumbar region, attended with abdominal distention. At the first examination I ventured the opinion that there was a limited obstruction of the ascending colon, but whether or not the tumor was a complication or the result of it I was unwilling to say until I could examine him when in his best condition. I advised him to call and see me then, and also to see Dr. Janeway in the meantime. He then informed me for the first time that he had already seen Dr. Janeway, and also many others in this city and in Brooklyn. At subsequent examinations it was easy to determine that the tumor first noticed was a floating kidney.

Laparotomy was proposed, to relieve the colon of the constriction, but owing to strong family objections it was

not performed until February 29, 1888, about eight months from the time I first saw him. Dr. Janeway, Dr. Dennis, and other physicians, whose names I do not now recall, were present at the operation. The family physician, too, Dr. —— was there. Before the operation was begun Dr. —— remarked that the patient was treated by him some three or four years before for what he believed to have been an acute attack of circumscribed peritonitis, located at the right side of the abdomen. The importance of this statement is obvious.

There is but little to be said of the operation itself. At the time of the operation the patient had recovered completely from the last attack.

The incision was made through the right linea semilunaris into the abdominal cavity. It was about five inches in length when fully extended, readily exposed the ascending colon, and disclosed the following conditions:

1. The hepatic flexure and the upper half of the ascending colon were bound to the parietal layer of the peritoneum, just outside of the line of incision.

2. Three fibrous bands were found passing nearly transversely across the intestine at its upper half, below the flexure. One of these bands was about one-fourth of an inch in width and caused a reduction in the lumen of the gut equal to about one-fourth of its diameter. The remaining two were narrower, ran more obliquely, and produced less constriction of the intestine. The right border of the omentum was adherent, at this situation, to a limited extent.

The bands were divided and removed, after ligaturing with catgut. The adhesions between the intestines and the abdominal wall were torn asunder with care, but without difficulty. A freely movable kidney was felt, though then lying in nearly the normal position. The caput coli and transverse colon were examined, but the examination disclosed nothing abnormal in connection with them. An unusually looped appearance of a limited portion of the small intestine was noticed just outside of the incision. The wound was closed, drained superficially, and dressed antiseptically. The patient made a continuous and complete recovery from the operation without an unfavorable incident.

Until the first week in May the patient considered that the operation had relieved him of his entire trouble. At this time the kidney became much enlarged, tender, and painful, and caused some pain when walking; it was pressing against the abdominal wall in contiguity with the lower half of the ascending colon.

In the course of three weeks the patient was apparently well again. The kidney, however, continued its peregrinations, especially with efforts of the patient while in the erect posture. During these and subsequent attacks the patient suffered from nervousness, debility, frequent nausea, loss of appetite and flesh, and occasional diarrhœa. The attacks were repeated, with varying intensity, once in three or four weeks. The following symptoms, however, that had been often present before the laparotomy did not again present themselves: 1, Vomiting; 2, abdominal distention; 3, unusual constipation; 4, mucous discharges from the bowels; (5) fæces not abnormal in shape nor in consistency.

After two or three months' suffering the patient entertained the proposition already made to "anchor the kidney," and finally consented to it, and on November 28, 1888, this operation was performed. A vertical incision was made just outside of the erector spinæ muscle, on the right side, from the lower border of the last rib, midway between its extremities, downward nearly to the crest of the ilium. The outer border of the quadratus lumborum was exposed without difficulty. The anterior surface of this muscle then served as a guide to the location of the kidney, which could not be felt at this time, even when firm pressure upon it was made in front. The anterior layer of the lumbar aponeurosis was then divided in a vertical direction. The kidney could then be felt with deep pressure, aided by counter-pressure. The transversalis fascia was then divided vertically to a similar extent. The kidney could then be easily felt as it moved upward and downward with each respiratory act. It could not be seen on account of its fatty surroundings. Firm pressure in front now forced the kidney against the open wound, along with its fatty capsule. This capsule was easily and quickly torn through, bringing the kidney fully into view. The divided edges of the capsule were grasped with the fingers and drawn through the wound with abdominal pressure, and about three inches of the capsule were removed from each side. The kidney was now pushed into the wound by gentle pressure, and the borders of the capsule were then drawn taut, turned over the edges of the entire external wound, and sewed firmly to it with carbolized silk carried through the entire depth of the lumbar tissues. This measure confined the kidney in the wound, but did not control entirely the movements of the kidney caused by the act of breathing. However, gentle pressure downward and backward on the kidney, from in front, readily confined the organ quietly in position. I should add that a stitch had been passed through the fibrous capsule of the organ before this had been quickly torn out through the fibrous capsule by the movements of the kidney. After the final sewing of the capsule the wound had about the following dimensions: Length, four inches, at the bottom; width, three-quarters of an inch. The bottom of the wound was composed entirely of kidney, covered by the fibrous capsule. The wound was then drained and packed with iodoform gauze, covered lightly with sublimate gauze, a counter-pressure pad applied over the kidney in front, and the whole confined in position with adhesive strips and bandages.

The patient made a rapid and continuous recovery without the intervention of an unfavorable symptom, and has promised to be present to-night for your inspection. Since the operation he has had no return of the old trouble, and has experienced no unusual sensations other than an occasional burning sensation at the seat of the kidney, and an indefinite sense of drawing, which I believe due to the contraction of the liberal cicatrix, upon which reliance is placed to retain the kidney in the new position, aided by the shortened and tense fatty capsule that nearly surrounds it.

SECONDARY SUTURE OF THE POSTERIOR TIBIAL NERVE WITH RAPID RESTORATION OF SENSATION AND MOTION.

By LAUGHLIN McFARLANE, M.D.,

PROFESSOR OF CLINICAL SURGERY, TORONTO UNIVERSITY, AND SURGEON TO THE TORONTO GENERAL HOSPITAL.

The history of nerve-suturing dates back for at least half a century, and well do I remember twenty-five years ago, when the late Dr. Beaumont primarily sutured the musculo-spiral nerve after its accidental division, while operating for non-union of a fracture of the humerus. The practice, however, seems to have fallen into disuse for many years. This, no doubt, was due to the very indifferent success of the operation. We can get little or no information on the subject in our ordinary text books. No doubt in the early times of the operation, the want of success was very often due to the mode of healing of the wound. In place of primary union it more commonly healed by a secondary effort of granulation with suppuration, and consequently the sutured ends of the nerve were held and firmly bound down by cicatricial tissue. Probably the suture holding the divided neurilemmæ, sloughed away long before union had taken place between the ends of the nerves. Within the last few years suturing has become more common, and the experience of many leading surgeons have been published and the results tabulated, so that we are now in a better position than formerly to form a correct idea of the practicability of the operation, both primary and secondary. This operation,

like many others, seems to have been revived on the introduction of aseptic surgery, and any success that we may have is due more to that fact than to any superior judgment or mechanical dexterity that we possess over the older surgeons.

At the present time, the unanimous verdict of the profession is strongly in favor of both primary and secondary suture, but the restoration of nerve-function is much more rapid in recent than in old cases. Mr. Bowlby has gone so far as to affirm that in no case has complete restoration of function ensued when operation has been delayed more than one year. This, however, is quite a mistake, as several recent reports show. In the case operated upon by myself, restoration of function followed an operation performed three years after the occurrence of the accident. The mistake, no doubt, was due to the fact that his report, or summary of cases, only reached as far as 1885. I will now give a résumé of the ultimate results of a number of published cases of secondary nerve-suture that have come under my observation.

Mr. Scoto, in a paper on nerve-suture, read before the surgical section of the Academy of Medicine in Ireland, relates the case of a young man twenty-one years of age, in which the median and ulnar nerves were completely divided. Eighteen weeks after the injury, the ulnar nerve was sutured, and in five days after the operation sensation was markedly improved. The median nerve was sutured in about ten months after the accident, and in three weeks the patient could distinguish the touch of a pin's point in all parts supplied by the nerves.

Mr. Bland Sutton sutured the median nerve ten weeks after division, and the patient recovered perfect use of his hand.

M. Lillaux relates a case in which he sutured the median nerve, and in three hours after the operation there was a partial return of sensibility. The patient recovered completely.

Ledderhose sutured the radial nerve six months after division. The function of the muscles was restored slowly, but perfectly. After a year, electro-mobility and sensation were found normal.

Mr. Bowlby gives a summary of all cases of secondary nerve-suture occurring in his own practice, as well as those that came under his observation in St. Bartholomew's Hospital, together with all cases recorded in surgical literature up to December, 1885, in all 67 cases, with the following result. Successful, 27; partially successful, 24; failures, 16.

Polaillon presented a case of primary and secondary nerve-suture, at a meeting of the Société de Chirurgie, on June 1, 1887. The case was that of a man who had a wound of the wrist, by which the cubitat and median nerves were severed, the primary suture of the nerves was a failure, but some time after secondary suture was done with perfect success. Time elapsing, not mentioned.

F. J. Shepherd, M.D., of Montreal, reports a case in the *Canada Medical and Surgical Journal*, of a man, aged fifty, who had his ulnar nerve cut with an axe, in the beginning of April, 1885. On the 24th of June, the nerve was sutured, that is, about ten weeks after the operation. The wound was firmly healed on July 8th. Sensation was good, but motion was deficient. He heard from him in January, 1886, when he was fast recovering the use of his arm, and had gone back to work.

Dr. Roddick, of Montreal, sutured the sciatic nerve, in May, 1884, seventeen months after its division. The immediate result was the healing of two ulcers on the foot. Sensation did not return for some time. Motion was not complete at the time the case was reported, but he was still improving, and could walk without a stick. I have now given a brief report of all the cases of secondary nerve-suture that I have been able to collect; but I have seen no account of any successful operation after so long an interval following the accident as in the case I am about to report. In this connection it might be well to call attention to the appearance of the ends of the divided nerve, after the lapse of one, two, or three years. It is generally stated that the proximal end of the nerve becomes bulbous, while the distal end is atrophical. This is not strictly correct, as in the case I operated on both ends of the nerve, "the upper, for upward of an inch, and the lower, for half an inch," were very much enlarged from fibrous thickening. This I do not regard as an unfavorable condition for operation, as it affords a better opportunity for bringing the divided ends together by giving a firmer hold for the suture. When the ends of the nerve are freshened the nerve proper can be seen occupying the centre of the thickened mass of a grayish-white color, thus showing that the thickening is principally from the neurilemmæ.

CASE.—David D——, aged twenty, on January 22, 1885, while working with another man scoring timber accidentally threw back his leg, and the axe in the hands of his companion struck him, making a deep clean cut in the lower and back part of his left leg, dividing the tendo-Achilles, posterior tibial artery, and nerve. The cut was bandaged and he was removed home when a doctor was called who redressed it, drawing it together with four stitches. Subsequent hæmorrhage took place, which was controlled by pressure. He was confined to his bed for sixteen weeks. The wound was treated without any extension of the foot on the leg, and, consequently, the tendon was lengthened about one inch from the cicatricial tissue. No attempt was made to ligature the artery or suture the nerve at the time.

The patient was unable to use his foot or attend to his work from the time of the accident in January, 1885, till he entered the hospital in May. 1888. The slightest pressure over the plantar surface of the foot gave rise to ulceration.

Condition on entering the hospital—The tendo-Achilles was found lengthened about one inch. The muscles above and below the seat of injury were considerably atrophied and quite flabby. A number of old cicatrices were to be seen on the heel and plantar surface of the foot, the result of several small ulcers that had appeared from time to time. There was a small ulcer occupying the plantar surface immediately beneath the internal cuneiform bone. The foot was quite warm and the circulation apparently good. Sensation in the dorsal aspect of the foot was good, but on the plantar surface was entirely gone.

The small ulcer on the foot could be pressed or handled in any way without giving rise to pain or tenderness. On the 4th of June an operation was performed for the purpose of suturing the ends of the nerve. The incision was made through the old cicatrix on a line with the nerve, when the divided ends were found embedded in the cicatricial tissue, and separated from each other for at least half an inch. Both ends were bulbous for a considerable distance. The ends were freshened and brought together with fine silk sutures. The upper segment of the nerve had to be well drawn down, and the foot fully extended on the leg before the ends could be brought together. The wound was then closed by silk sutures and dressed with dry antiseptic dressings. The limb was then placed on a posterior splint with a footboard and the foot extended to its fullest extent.

June 5th.—Temperature, 100° F.; considerable pain; retention of urine relieved by catheter.

June 6th.—Patient quite easy. Temperature, 99 °F. Catheter has still to be used. There is sensation in the foot this morning. The prick of a pin can be felt over all the tract supplied by the posterior tibial nerve. The small ulcer is painful.

June 13th.—Ulcer completely healed. The sensation is fairly good. Complains of slight pain in the leg and foot if moved suddenly.

July 3d.—Has a fair amount of movement in the ankle-joint, not able yet to control movement of toes, as any pressure on end causes them to be suddenly extended; quick movement of the ankle causes a jerking painful

sensation. Patient with closed eyes is able to locate the position of my finger on foot with considerable accuracy, and at once responded when a needle was applied.

July 4th.—Patient left for home this A.M., wound completely healed. I heard from him on the 28th of July, when he informed me that both sensation and motion were gradually improving and that he could now walk for a short distance with considerable comfort; as he expressed it, "My foot is first class, and am only waiting for further instructions to use it more."

On September 7, 1888, my clinical clerk received a letter from him in which he says, "My foot is doing first class, I have a good deal of feeling in it, and can walk splendidly without crutch or stick. There has been no ulcers since I left Toronto. I have no pain except after walking a long distance, when it feels a little sore and tired, but this soon passes away."

The length of time elapsing between the accident and the suturing of the nerve, viz.: two years and six months, and the rapidity with which sensation and motion returned is my only excuse for publishing the case.

Clinical Department.

MATERNAL IMPRESSIONS.

DR. R. GROSS, of Eureka, Cal., writes: "In THE MEDICAL RECORD of November 17, 1888, page 607, there is a communication from E. P. Murdock, of Chicago, Ill., in which he claims that searchers after truth are 'made tired'—or 'weary,' as he puts it—because any medical man who claims to be educated should entertain an idea that maternal impressions can in any way leave their mark on the child *in utero*. I am aware of the fact that physiologists hold that, when the ovum has once been cast off from the ovary of the mother, it is no longer an integral part of her body, but becomes pseudo-parasitical, and argue from this that maternal impressions cannot influence the fœtus, because that can only be done through the influence of the nervous system. Be that as it may, the two following cases make me a believer that maternal impressions can, and do, leave an impress in some inexplicable way, in some cases.

"In the winter of 1871 or 1872—I have not my case-book at hand, consequently cannot give the exact date—I attended in confinement a Mrs. R——, in New Brunswick, Canada. As soon as the child was born she asked me if the babe had a hare-lip? I said 'Yes.' Then she said: 'Oh, dear me, I can never have a child without that deformity. When I was like for the third baby before this I saw two women fighting, and one struck the other with a piece of brick on the upper lip and cut a gash in it. I was very much frightened, and when my babe was born it had a hare-lip. The next babe was just the same, and Dr. T——, who attended me, said all my children would be marked in the same way. From the moment I find I am in the family way I begin to see my child with a hare-lip, and I can't get my mind off it.'

"I asked her if there were any cases of hare-lip in her or her husband's family? She replied, 'No.' Then I said, 'You will never have another child with a hare-lip; there is no such thing on record—it is impossible for a woman to have more than three hare-lipped children.' The same thing was authoritatively promulgated to the husband and the old ladies in the neighborhood. I knew of two children being born subsequently to her without any deformity.

"Second. A year afterward I attended a young woman in Calais, Me., on the birth of her first child. As soon as I could leave the mother the nurse called my attention—in an adjoining room—to two long narrow blisters on the back of one of the child's forearms.

"The raised cuticle was still present; on removing it the underlying surface was still red, presenting all the appearances of recently healed blisters.

"The mother knew nothing of this, neither did she hear the conversation between me and the nurse. I asked her if anything had happened recently to herself, or in her presence. After thinking some time, she said: 'About three weeks since a little child, where I was, fell with its bare arm on the stove and burned it on its outer portion.' When shown the marks on the babe, she said they were similar to what was on the child.

"Although I have often made light of a woman's fears when she told me that she had 'had a fright, and was sure her babe would be marked,' and I cannot recollect an instance where I assured the woman that her fears were groundless that the result did not verify my prophecy, still, the two foregoing cases leave me convinced that in certain cases, in nervous women, shocks may leave an impress on the fœtus *in utero*."

Progress of Medical Science.

POISONING FROM AN EXCESSIVE DOSE OF SULPHUR.—A correspondent of the *British Medical Journal* records the following observation: J. S——, mechanic, had suffered for some time from externalp iles. He applied to a chemist, who sold him a pennyworth (one ounce) of sublimed sulphur, with directions to take it overnight. This was on Monday; he took the dose, and repeated it on Tuesday. On Wednesday the doctor was called in hurriedly, as the man was supposed to be dying. He found him lying on his back in bed, utterly prostrate and partially insensible. The patient had had repeated rigors during the day, and in lucid intervals complained of intense frontal and vertical headache, with aching, griping pains in the bowels. His symptoms on examination were briefly: Temperature, 104°; pulse hard and quick (120 per minute); tongue dry and deeply furred; breath fetid, and smelling strongly of sulphuretted hydrogen; pupils strongly contracted and insensible to light; skin bathed in a profuse clammy perspiration; abdomen tympanitic and very tender on slight pressure. He retched and vomited almost continuously, and was several times purged—both vomit and dejecta being composed mainly of slightly bloody mucus mixed with fine particles of sulphur. The urine he had passed (in driblets) also contained blood. Having ascertained the cause of his illness, the doctor had hot fomentations applied to the abdomen, and administered a moderately large dose of castor-oil. The next day he was still purged, but most of the irritant sulphur appeared to have been eliminated, so he considered it safe to treat the case as one of acute enteritis, and put him under a course of opiates. He remained in bed for about a week, and made an uninterrupted recovery. The case appears interesting since sulphur is not usually counted as a poison. The dose taken (two ounces) was very large, and the symptoms produced were certainly those of a strongly irritant poison.

SUCCESSFUL VAGINAL HYSTERECTOMY FOR CARCINOMA UTERI.—Dr. William H. Wathen, of Louisville, Ky., read a paper with this title before the Southern Surgical and Gynæcological Society, at Birmingham, Ala., December 5, 1888. The patient presented herself for examination in August; she was thirty-four years of age, and the mother of five children. From the history given it was concluded that the disease had begun twelve or eighteen months previous. The uterus was in normal position, perfectly movable, and no enlargement of pelvic or other glands could be detected. Carcinoma of the cervix uteri extended up the endometrium, but did not involve the vagina or any of the uterine adnexa. She was suffering with almost constant bleeding, the blood mixed with offensive matter. Her digestive and assimilative functions were bad, she was rapidly losing flesh,

and the general appearance indicated approaching cachexia. The operation was performed October 9th, at the Norton Infirmary, of Louisville, as soon as her local and general condition could be placed in good condition. She was prepared for the operation by being well purged, carefully bathed, the hair cut from the pubes, and the parts washed with ether and a $\frac{1}{2000}$ solution of bichloride of mercury, and the vagina washed with two gallons of hot water which had been boiled. The instruments and sponges were placed by the nurse in a weak carbolic acid solution. The patient was placed in an exaggerated lithotomy position, chloroform administered, and the neck of the uterus exposed by a Sims speculum and retractors, and drawn to the vulva with a heavy vulsellum forceps. The vagina was cut away from the cervix about one-fourth inch from its attachment, and two or three small bleeding arteries secured by catch-forceps. The pouch of Douglas was opened, and all posterior attachments of the uterus rapidly separated; then the uterus was carefully dissected from the bladder, great care being used to avoid wounding this organ or the ureters. Finally, all that held the uterus in position had been divided except the folds of the broad ligament. The index-finger was now well hooked over the left ligament, and it was secured at a distance from the uterus by a catch-forceps of Dr. Wathen's device. The right ligament was clamped in the same way; both were then divided by the scissors near the clamps, and the uterus, ovaries, and tubes were pulled away through the vulva. The uterus was not inverted, and was removed in twenty minutes; not more than one or two ounces of blood were lost during the operation, and none after it. To prevent the possibility of hemorrhage, all bleeding surfaces or points were caught in catch-forceps, so that when the operation was over eight pairs were left in the vagina. The small ones were removed in twenty-eight hours, and the two large ones clamping the broad ligaments in fifty-two hours. A small pledget of sublimated cotton was introduced into the vagina to hold the forceps apart and assist drainage, the vulva well covered with absorbent cotton and a T-bandage applied. No sutures were used to unite surfaces, and the vaginal vault was left open. No vaginal washes were used, but the dressing of cotton removed twice daily, and the external parts carefully cleansed. Her pulse after the operation and the first day was sixty beats per minute; it then ranged from sixty to ninety, seldom above seventy-five. Her temperature reached nearly 101° F. the second day, owing to the irritability caused by the presence of the forceps, and then ranged from 98° to 100° F. At no time was there any shock or sepsis, and she made an uninterrupted recovery, being out of bed the fifteenth day, and leaving the Infirmary the nineteenth day after the operation. Dr. Wathen believes the mortality in vaginal hysterectomy can be reduced as low as in ovariotomy, and that by the use of clamps the technique of the operation is so simplified and improved that the loss of blood is no longer an important factor, as the uterus, etc., can be removed in from ten to twenty minutes.

THE MEDICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.—A paper with this title was read by Dr. Bedford Brown, at the meeting of the Southern Surgical and Gynecological Society, in Birmingham, Ala., December 5, 1888. The author gave the results of his observation of twenty-seven cases which had occurred in his practice during the past thirty-seven years. In these cases are included all classes, from the most grave, accompanied by alarming hemorrhagic tendencies, peritonitis, septicæmia, and general prostration, to those in which the system never sympathized to any marked degree. Some of these had remained under his treatment as long as twelve to fifteen years, some for five or six years, others a shorter time, and in all there had been improvement, at least one-third amounting to positive recovery. Reports of a number of interesting cases were given in which the lacto-phosphates and hypophosphites were freely used, in some cases in connection with ergot to repress hemorrhages. In cases of excessive hemorrhage he believes the phosphatic treatment, persistently pursued, ergotine and strychnia internally, and the local application of iodine and the extract or normal liquid ergot alternately every third day, will so impress the general and local circulation and the process of nutrition as to regulate the hemorrhagic tendency. To produce favorable results the treatment must be pursued systematically, regularly, perseveringly, and continuously. Several cases of acute glandular affections were cited in which the effects of the hypophosphites and lacto-phosphates were really marvellous, and the conclusion reached by Dr. Brown was that they must exert a very great influence on the functions of that system as well as on the metamorphosis of tissue by promoting its disintegration and removal. He dwelt more forcibly and specially on the necessity of the rapid and thorough saturation of the circulation with the phosphates of lime and soda, as a means of restoring the lost equilibrium of nutrition, arresting increased cell proliferation and exudation, and promoting the absorption. He contends these agents have not heretofore been given in sufficient quantities to regulate the process of nutrition. In grave and serious cases he has administered as much as a drachm of the syrup of the hypophosphites every two or three hours, and two drachms of the lacto-phosphates three times daily until the object was attained. In summing up the results of the medical treatment of fibroid tumors it may be stated that the continuous administration of ergot, in the form of ergotine or fluid extract, retards the fibroid growth, lessens the tendency to hemorrhage, and in certain states of fibroid growth, on occasion of hemorrhage, given hypodermically, or internally, will arrest it. But at an advanced stage, when the growth of submucous fibroid becomes very great, and the walls of the uterus have become very thin and attenuated from over-distention and absorption and paralysis of uterine muscle, then the ergot ceases to act as a hæmostatic. The fluid extract of hydrastis acts on the fibroid growth to a limited extent. Local treatment by means of iodine and ergot applied extensively over the cervix and roof of the vagina gives important therapeutic aid. By a judicious and timely combination of the various agents the author believes that the great majority, if not all cases of uterine fibroid, may be shorn of their worst features; that the sufferings of those so afflicted may be greatly alleviated; that life may be prolonged; that all may be benefited, and certain proportions cured. He asserts that benefit has resulted from treatment in every case when the patient was under charge long enough to get fully under the influence of medical treatment. Hence he is convinced, by a long and not inconsiderable personal experience, that medicine can do much, and is capable of doing still more in the future, for the benefit and relief of these cases.

EFFEMINACY AND ANÆSTHETICS.—Miss Lynn Linton thinks that men are becoming effeminate, and lays the blame in part to anæsthetics. She is particularly severe upon the Italians, of whom she says: "Nothing differs so much in races as tenacity of life. A southern Italian dies of a shock to his nervous system which would not do more than give an Englishman a headache. He takes to his bed for a fit of passion, and is seriously ill when he "makes bad blood." He has become as brittle as a star-fish, as invertebrate as a sea-cucumber; and what climate and careless ease of living, the want of hard work and the insufficient food resulting, the soft self-indulgence of idleness, and the absence of that hardening process which is got by struggling with evil conditions—what all these have done for him our moral effeminacy is doing for us; and if we are not on the alert and do not keep up our fighting blood as men should, we shall become just as molluscous, as invertebrate, and as brittle as those degenerate descendants of warlike progenitors."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 12, 1889.

CREASOTE IN THE TREATMENT OF PHTHISIS PULMONALIS.

IT is but natural that a disease which is ever present among us should receive the uninterrupted attention of physicians. The discovery of Koch, which was at first supposed to be barren of practical results, especially as regards treatment, has undoubtedly given a mighty impulse to the search for rational phthisiotherapy. While all physicians are agreed as to the utility of improving nutrition in phthisis, some believe that drugs are entirely useless, except to afford symptomatic relief. Most physicians, however, continue to employ medicines in a more or less tentative way.

Of individual drugs, creasote has lately been urged in a manner which really appears to bespeak for this substance considerable power for good, more particularly in the earlier stages of the disease. To the European publications touching the value of creasote in phthisis THE RECORD has repeatedly referred. In our own country the subject has quite recently received the attention of several physicians, notably of Drs. Austin Flint and Beverley Robinson. The former of these has published, in the *New York Medical Journal*, a report of ten cases of consumption treated by the use of creasote. From his study of these cases he is led to advance the opinion that creasote by the stomach and by inhalation, in cases of solidification without cavities, effects prompt and decided improvement in all phthisical symptoms, with increase in appetite, weight, and strength, even with surroundings much less favorable than would obtain in many cases in private practice.

In cases with small cavities much less improvement is to be looked for, but some benefit may be expected.

In cases with large cavities the treatment seems to have little more than a palliative influence.

His observations are defective as regards the influence of the treatment upon the bacilli. In one case, with large cavities, it was noted that the number of bacilli was diminished. No other examinations for bacilli were made during or after treatment.

No estimate was made of the relative value of creasote taken into the stomach. As regards inhalations, it is assumed that the chief benefit was derived from the creasote, the spirit of chloroform and the alcohol rendering this agent more volatile, and soothing the mucous surfaces. The inhaled vapor undoubtedly penetrated by diffusion as far as the air-cells. It is by diffusion that fresh air, anæsthetic vapors, etc., penetrate the lungs, and cases of pneumonokoniosis illustrate the fact that even solid particles may be carried to the pulmonary vesicles.

He has also employed the method of inhalation, conjoined with other treatment, in private practice, with good results.

From the observation of a much larger number of cases Dr. Robinson (*The American Journal of the Medical Sciences*, January, 1889) is convinced that "we have in beechwood creasote a remedy of great value in the treatment of pulmonary phthisis, particularly during the first stage. Not only does it lessen or cure cough, diminish, favorably change, and occasionally stop sputa, and often relieve dyspnœa; but it also frequently increases appetite, promotes nutrition, and arrests night-sweats. It does not occasion hæmoptysis, and rarely causes disturbance of the stomach or bowels, except in cases in which it is given in too large doses."

Dr. Robinson also believes that there is a fair amount of evidence to show that by its long-continued judicious use, it may and will modify favorably the local changes in pulmonary phthisis. Whether it has any antiparasitic effect remains to be determined in a more accurate manner. It is certainly, according to this author, an unobjectionable medicament from any point of view. It is easy of administration, it is adapted to the majority of sufferers from pulmonary phthisis everywhere; it may be used with some advantage in all stages of this disease, and finally, it has proven itself superior to any other medicinal treatment with which he is familiar.

Dr. Robinson employs creasote both internally and by inhalation, the combined method being, in his judgment, the most efficient one. The ordinary dose has been half a minim repeated every two or three hours. English beechwood creasote is given the preference over other preparations on account of its purity. It is employed with whiskey and glycerine according to the following formula:

℞. Creasote (beechwood)..... ℥ vj.
Glycerine..... ʒ j.
Whiskey..... ..... ʒ ij.
M. Sig.: As directed.

From what has been written on the creasote treatment of phthisis, we may feel reasonably certain that the remedy is not devoid of utility in its proper sphere. The climatic treatment of consumption is, after all, but the rich man's remedy. By far the larger number of phthisical patients will continue to seek relief from their ailments by the use of medicines, and creasote will doubtless soon be employed on a sufficiently large scale to definitely determine its true value.

CAFFEINE IN PULMONARY AFFECTIONS.

ALTHOUGH caffeine has long been recognized as an excellent heart tonic, and has been so used for a number of years, it is only recently that attention has been called to its value in disease of the respiratory organs. It is more particularly in those affections of the lungs in which there is need also of a cardiac stimulant that the drug has been found useful. In an article in the *Berliner Klinische Wochenschrift*, Nos. 25 and 26, 1888, Dr. C. Gempt, reports several cases of pulmonary disease in which this

drug was used with beneficial effect. He formulates the results of his experience in the following conclusions:

1. The administration of caffeine is indicated in cases of acute lobar pneumonia as soon as commencing heart failure manifests itself by a very rapid or irregular pulse.

2. The drug should be given, if possible, before the actual symptoms of collapse appear, although even after this condition has set in, unexpectedly it may be, the indication for the remedy is still urgent, and the results of its exhibition are often most gratifying.

3. In cases in which there already exists valvular disease or cardiac weakness, the administration of caffeine should be begun at the very onset of the pulmonary affection. The same is true where pneumonia attacks those given to alcoholic excess, or the aged.

4. The effects of the remedy are seen in diminished frequency of the pulse and respiration, increase of arterial pressure, lowering of the temperature, and improvement in the subjective sensations of the patient.

5. Although the action of the remedy is rapid, nevertheless, in some cases of especial gravity, it is better to administer it by subcutaneous injection. After the defervescence the drug need be given for but a short time only.

6. The same indications for the use of caffeine are present in atelectasis, pulmonary hypostasis, emphysema, and asthmatic conditions.

CREOLINE AND THE COMMA-BACILLUS.

Creoline is one of the most recent of the many new antiseptic substances that have of late years been brought to the notice of the profession. As is the case with most new remedies, the advocates of this drug claim for it the advantage of great efficacy and harmlessness to the animal organism; but whether these claims will be substantiated by a more extended trial remains to be seen. Some experimenters have already asserted that the substance is capable of giving rise to toxic symptoms in even moderate doses, and doubtless it will be found that care is necessary in its administration as well as in that of other powerful antiseptics.

Drs. Sirena and Alessi have made a series of experiments with creoline to determine its action upon the comma-bacillus of Koch, and have been led by the results obtained to place great hopes upon it as an efficient remedy in cholera (*La Riforma Medica*, Nos. 257 and 258, 1888). It is not necessary to give the details of these experiments, which may be found in the original article, and we will reproduce here merely the following conclusions which the authors have reached, as a result of their labors:

They state that the addition of from eight to ten drops of a three per cent. aqueous solution of creoline is sufficient to completely sterilize, within five minutes, a pure culture in broth of the comma-bacillus. From one to four drops of the same solution, added to ninety drops of a broth culture, will prevent the development of the comma-bacillus. From one to three drops of a one per cent. solution retard the development of the micro-organisms, and four drops or more prevent it completely.

The solutions of creoline are apt to lose their efficacy in time, hence it is necessary to use fresh solutions whenever a certain and speedy action is desired.

The authors regard creoline as an antiseptic of great value, and recommend that it be employed in the treatment of cholera. They believe also—and this belief they hope to fortify by experiments in the early future—that the remedy will be found of great efficacy in the treatment of tuberculosis.

THE ST. PETERSBURG ACADEMY OF MEDICINE.

In a series of articles by M. Huchard, on "Medicine in Russia," appearing in the *Revue Général de Clinique et de Thérapeutique*, there is an account of the St. Petersburg Academy of Medicine, which is an institution differing so much from societies of the same name with which we in this country are familiar, that, possibly, a brief description of its constitution and aims may prove not uninteresting.

This Academy is not such as we understand it, a scientific association of physicians founded for the mutual improvement of its members, but is rather a combined medical school and hospital. There are twenty-three regular professors, receiving a salary of about $1,500 each, and four others at a salary of $1,000. The appointments are competitive. There are also about fifty privatdocenten, who give courses of instruction to students, but without pay. Students desiring to enter the Academy must present the *testimonium maturitatis* certifying that they have passed eight years in the *gymnasium*, and must submit to an examination at the end of each year. The students, during their last three years in the school, receive, on condition of serving four and a half years in the army after their graduation, an annual stipend of $180. Each year the seven graduates who have passed the best examination have the right to remain three years longer in the Academy, at a salary of $600, in order to pursue further their studies in physiology or pathology, as they may elect. At the end of this period, the three who have obtained the highest rank are sent abroad to study for two years, receiving in the meantime a salary of $1,000. Upon their return they may study another year in the Academy. It is from among these that the professors are usually chosen, the other graduates ordinarily entering the army.

At the expiration of four years' service as military surgeons, fifty are selected—twenty-five physicians and twenty five surgeons—to return to the Academy in order to study two years longer, after which time they return to the army receiving a higher rank.

The hospital internes are graduates in medicine. They are appointed for no particular term of service, but may retain their positions as long as they desire. The chiefs of clinic are the professors' assistants, and perform the duties of the latter in their absence. They receive an annual salary of $600, and retain their positions at the will of the professors under whom they serve.

The Military Hospital of the Academy has accommodations for eight hundred patients. There are four medical clinics, which are graded, two being for third-year students and one each for fourth and fifth year students. This principle of grading is carried out also in the gynecological and special clinics, there being one of each for fourth and

fifth year students respectively. The appointments of these clinics, especially of the gynecological, are excellent.

Professor Slavyanski's gynecological clinic contains fifty beds. The lying-in ward is large and scrupulously clean. All the tables are covered with slabs of glass, the floor is of hard wood varnished, and the corners are rounded to facilitate the removal of dust and thorough antiseptic cleansing. A second ward, finished in the same way, is provided, to which the patients may be moved in case there should be an outbreak of infectious disease. Adjoining these wards is a little room where the newly born children are baptized. There is a separate ward for patients suffering from cancer of the uterus or other diseases attended with discharges of a bad odor. There are also separate rooms for minor and major operations, the latter being well lighted and provided with an apparatus by means of which the walls, ceiling, and floor can be rapidly washed. The gynecological wards contain each not more than five or six beds, some having but two. Professor Slavyanski's private room is luxuriously furnished, and on the wall the place of honor is occupied by the portrait of Ambodik, who is regarded as the first Russian accoucheur, the practice of obstetrics having been before his time wholly in the hands of the Germans.

The library of the Academy, which is under the direction of Dr. Kondratiev, contains upward of one hundred and ten thousand volumes and five hundred periodicals. Each student is allowed to take two books at a time from the library, and to keep them for a month. Special working-rooms for the professor and students are provided, where they can consult any of the works in the library between the hours of eleven and five.

PRIZE-MONEY FOR SCIENTIFIC WORK.

The Paris Académie de Médecine offers prizes for the year 1889 to the amount of over thirty-five thousand francs ($7,000). This sum is distributed in twenty-one special prizes, varying from $100 to $1,000 each.

If money could purchase scientific zeal, the rewards offered by the Académie ought to be very fruitful in results. As a matter of fact, however, one hears very little of these highly paid prize-essays which the Paris Académie stimulates into existence.

The offering of prize-money to scientific workers is a thing which has its field of usefulness, but this field is a narrow one. The money is generally better applied in encouraging and supporting those whose industry and skill in scientific work are known, or in expending it to secure the investigation of certain definite problems.

A medical organization which has $7,000 to give away annually is much to be envied. It represents more than the total income of any American society, with one or two exceptions. As this money was received chiefly in the form of legacies for a specific purpose, the prizes no doubt have to be offered from year to year, with the usual relatively barren results.

AN ATTACK ON ABORTIONISTS.

No more extraordinary performance has occurred in years than that at present going on in Chicago regarding the repression of the practice of infanticide and abortion. A newspaper of that city has undertaken to agitate publicly the subject of abortion, and to bring to justice those persons who practise it in Chicago. For this purpose it engaged a "girl reporter," who went around among various doctors and midwives. She represented herself to be a single woman, who, through indiscretion, had become pregnant. Taking notes as she went, she finally secured a list of doctors who would not, and of doctors and midwives who would, perform some operation upon her. This list is published in full upon the editorial page of the paper in question, while the news columns are filled with the details of the conversations held regarding her condition.

A letter from the President of the Medico-Legal Society endorsing the work of the *Times*, and another from the President of the Chicago Medical Society, headed with a full list of the faculty of Rush Medical College, are also published most prominently on the editorial page.

The whole performance has an offensively sensational appearance, and we regret to find our Chicago brethren thus aiding and abetting such an example of noisy and nasty journalism. While the exposure may have some temporary benefit in making professional abortionists more careful, it is very doubtful if such methods are permanently useful. On the other hand, the publicity given to the details of abortionists' methods may eventually actually increase the evil which it is so desirable to abate.

News of the Week.

The Resignation of Dr. H. T. Formad, as junior professor of pathology and anatomy at the University of Pennsylvania, is announced. The direct cause of Dr. Formad's resignation was the promotion over him of Dr. John Guitéras, United States Navy, to succeed Professor Tyson.—*Boston Medical and Surgical Journal.*

The Visit of Sir Morell Mackenzie to Edinburgh stirred up a considerable amount of ill-feeling among the medical element in the University. The professors of the University did not—cordially, at all events—give their countenance to Sir Morell's two meetings. The students did; and they resented the coolness of their teachers.

Dr. James A. Emmerton, of Salem, Mass., died on December 31st, aged fifty-four. He was graduated from Harvard, and during the war he served as an army surgeon. He was assistant surgeon at the New York State Lunatic Asylum at Utica in 1866–67.

A Memorial Hospital has been opened at Long Branch.

The Hospital Saturday and Sunday Collection had reached the sum of $25,000 at last reports.

Calage, or wedging of the body in the berth, is said by M. Marcel Baudouin to be a sure preventive of seasickness, at least in many cases. M. Baudouin advises the patient to lie upon one side and have the body thoroughly bolstered and braced so that it moves with the ship.

California Medical Colleges.—The Cooper Medical College held its annual commencement on November 18th, and graduated a class of fourteen. The Medical Department of the University of California held its commencement on November 16th, and graduated a class of ten.

"The Pacific Medical and Surgical Journal."—Dr. William S. Whitwell, who has ably edited this journal, has transferred its management and ownership to Dr. D. A. Hodghead.

Claimants for Vaccine against Cholera. — Dr. D. J. Ferrán, whose claims to the discovery of a vaccine against cholera were widely advertised some three years ago, transmits a request to the Paris Académie des Sciences that it authorize an investigation of the Ferrán method, as well as that of Dr. Gamaleïa, recently announced. Dr. Ferrán, whose skill is doubted more than his sincerity, also claims priority over Dr. Gamaleïa in regard to the discovery of the cholera vaccine.

An Attack on Pork.—Our esteemed contemporary, *Daniel's Texas Medical Journal*, after having let the world roll round in its old bad way for some time, has suddenly roused itself and made a violent attack upon the hog. The *Journal* has reason to believe that Moses was an advanced sanitarian, and would, as it seems, add the great law-giver's fiat against pork to the eternal interdictments of the decalogue. Exactly why Texas is thus trying subtly to undermine the prosperity of Cincinnati we cannot say. Pork is not a meat that slips into the circulation without some strain on the gastro-enteric secretions; but it is no worse than veal, nor certain varieties of the Texas steer which find their way eastward. The pig is likely to be with us indefinitely, and it will be better to improve his habits than exterminate him. We fear that the Austin butchers have been working some of the smaller domestic animals into our contemporary's morning sausages.

Removal of Tumor of the Brain.—Dr. E. H. Bradford removed a tumor weighing about nine drachms from the brain of a patient at the Boston City Hospital recently. The symptoms, which had lasted about two years, were headache and double optic neuritis, with some vertigo and vomiting, tactile hemianæsthesia, most marked in the left arm, and loss of muscular sense in the arm, paralysis of the left arm, and partial paralysis of the leg, with contracture and exaggerated tendon reflexes and convulsions, beginning with a sensory aura in the left wrist and clonic spasm of the left hand. The patient died three-quarters of an hour after the operation, from shock.

Northwestern Medical and Surgical Society of New York.—At the Annual Meeting of the Northwestern Medical and Surgical Society, held on the 19th ultimo, the following officers were elected for the year: *For President*, Dr. A. M. Jacobus; *for Vice-President*, Dr. S. Baruch; *for Secretary*, Dr. Edward S. Peck.

Hysterorrhaphy.—In the article on this subject, on page 756, the sentence, "The fame of this gynecologist," etc., should read, "the fame of the gynecologist." The implied personal reference distorts the meaning of the sentence.

A Provident Dispensary in Philadelphia.—It has recently been announced, says *The Medical and Surgical Reporter*, by advertisement in the daily papers and otherwise, that a so-called "Provident Medical Service" has been organized in Philadelphia, with a rather imposing Board of Managers and a well-known medical man as President. The affair is a dispensary, modelled on the lines of what are called "Provident Dispensaries" in London. Persons treated here are to be charged the small sum of twenty-five cents for each consultation. The idea is that this will encourage those who are too poor to pay the usual fees, at least to pay something; and that thus worthy people in straitened circumstances will be saved from the disgrace of pauperism.

Death of Dr. Thomas Goodwillie, of Vernon, Vt.—Dr. Thomas Goodwillie, brother of Dr. D. H. Goodwillie, of this city, died of pneumonia at his residence, Vernon, Vt., in the forty-eighth year of his age. He graduated from the Classical and Medical Departments of Dartmouth College, and spent his professional life in Vernon. A widow and three daughters survive him.

The New York Pathological Society.—The following officers were elected at the annual meeting of this Society, held on January 9, 1889: *President*, Dr. William P. Northrup; *Vice-President*, Dr. H. M. Biggs; *Secretary*, Dr. T. L. Stedman; *Treasurer*, Dr. J. H. Hinton; *Editor*, Dr. J. C. Peters; *Committee on Admission and Ethics*, Drs. J. C. Peters, L. H. Sayre, H. P. Loomis, Walter Mendelson, and L. Emmet Holt; *Committee on Publication*, Drs. G. C. Freeborn and W. B. James; *Committee on Microscopy*, Drs. Ira Van Gieson, H. P. Loomis, and John S. Ely.

A Farewell Banquet to Dr. John W. Hunt, of Jersey City.—The numerous professional and lay friends of Dr. Hunt gave him a farewell banquet on Monday evening, at Taylor's Hotel, Jersey City, on the occasion of his changing his residence to Los Angelos, Cal., in consequence of the feeble health of Mrs. Hunt. Mayor Cleveland of Jersey City presided, and introduced the toasting by a history of the career of Dr. Hunt during his residence for a quarter of a century in Jersey City, glancing at his creditable war-record, his founding of the Jersey City Hospital, and his interest in charitable enterprises. Dr. Hunt replied in some feeling remarks. Letters of regret were read by Dr. J. H. Vondy from Drs. George F. Shrady, Lewis A. Sayre, J. R. Leaming, A. B. Mott, and R. F. Weir, of New York, after which speeches were made by Dr. J. W. S. Gouley, of New York, Dr. Smith, of Brooklyn, Ex-Mayor Collins, Major Pangborn, and the Rev. Mr. Scudder.

The Eschscholtzia Californica.—M. Bardet and M. Adrian have examined the American plant called *Eschscholtzia Californica*, and they find that it really contains morphine, and this is the first time that a plant of any other order than the *Papaveraceæ* has been found to contain that alkaloid. It contains also another base, together with a glucoside, which may be very important when their characters have been studied. In any case the drug should be a valuable aid in replacing the opium alkaloid when necessary.—*Paris Cor. New York Medical Journal*, December 22, 1888.

Leprosy Inoculated in a Criminal.—Some time ago, in commenting upon the bacteriological work of Dr. Arning, we stated that he had tested the question of the inoculability of leprosy practically upon a convict, at Kearm. The operation was done in November, 1885. It is now stated that the man is suffering from tubercular leprosy.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 20, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT stated that Dr. T. M. Cheesman had recently donated one hundred and fourteen valuable volumes to the library of the Academy.

Dr. Francis V. White, formerly an active member, then a non-resident member, was, in accordance with his desire, reinstated to active membership.

DR. THOMAS E. SATTERTHWAITE read a paper entitled,

A NEW STUDY OF LOBAR PNEUMONIA, WITH DEDUCTIONS FROM AN ANALYSIS OF FIFTY-SIX FATAL CASES.

Pneumonia was said to be epidemic in ancient times, and epidemics, which resembled to some extent pneumonia as now seen, were described in the sixteenth century and afterward; but in the majority of cases the diagnosis was not verified by post-mortem examinations, which were rare in the earlier days of medicine. Epidemic pneumonia does not prevail to any great extent during the present time, yet a certain number of facts sustain the theory that it is occasionally epidemic.

His paper would be devoted to the subject of lobar pneumonia in its primary and secondary forms; the first form he called acuté lobar pneumonia, and the other secondary pneumonia.

To avoid obscurity, however, he mentioned the principal types of pneumonia, as follows: 1, acute lobar; 2, secondary lobar; 3, embolic lobar; 4, bronchial-lobular; 5, the interstitial pneumonia of heart disease.

He preferred the term acute lobar to that of croupous. This was the most common form of pneumonia. In one hundred fatal cases taken from his hospital and private records, the several varieties were represented as follows: acute lobar, thirty-six per cent.; secondary lobar, nineteen per cent.; bronchial-lobular, twenty per cent.; interstitial of heart disease, seven per cent. He had found it most common in males, and most frequently between the years thirty and eighty. It was more particularly a disease of middle life. It occurred nearly altogether in northern and middle latitudes. When the disease originated in one lung it usually selected the right. In his cases it usually commenced in a lower lobe.

The first stage was commonly called the stage of engorgement, the whole tissue being increased in volume, infiltrated with a serous fluid, with more or less transudation of blood from the vessels. The second stage was called the stage of red hepatization, the lung being of a deep red color, unyielding to the touch, and difficult to distinguish from an inflamed liver. It contained little air if any, and almost no fluid. Its cut surface had a rather rough or granular and dull aspect, each speck corresponding to an air-vesicle or bronchiole filled with a firm pellet, consisting of blood-cells and epithelium mixed with fibrine. In the third stage, that of gray hepatization, the reddish tint had yielded to a dirty gray, at first tinged with brown, and then with yellow; the tissue was softer, and on pressure exuded a small amount of fluid; the walls of the blood-vessels were studded with leucocytes; in many cases there was dark pigmentation of the interlobular spaces. The lung might weigh five or six times its normal weight.

In his experience the order of the symptoms was as follows: 1, pain, prostration, and cough; 2, a severe chill; 3, nausea; 4, rise of temperature.

Instead of a severe chill there might be only chilly sensations. Within a few hours the temperature commonly rose to 103° or 104° F. One of the early signs, though seldom the earliest, was fine crepitation. It was heard only during inspiration. It was not a sign which was absolutely essential in diagnosis. Occasionally it lasted the full course of the disease. As soon as the second stage began there was dulness on percussion, with bronchial breathing and bronchophony; also increased vocal fremitus. In the fourth stage, that of resolution, there was returning crepitant râle.

The author was inclined to think that the locality of the affection, whether in the upper or lower lobe, did not influence the production of cough or affect its character. In old people cough might be absent. Sometimes it was the first symptom. The expectoration was peculiarly tenacious and variously colored. One looked for the characteristic prune-juice color, but it was sometimes absent; it might be red, black, green, or colorless. The characteristic sputum of pneumonia had three qualities. color, consistence, and coalescence. This sputum might be present on the first day, or not until the third or fourth, but the characteristic sputum was not always present, and it might occur occasionally when no pneumonia existed, as in nasal or pharyngeal catarrh with hemorrhage, or acute laryngitis, as in a case which he had observed recently. As resolution approached, the sputum was apt to be yellowish in color.

Diarrhœa was often present, also nausea and vomiting. The urine was often scanty. There was a difference of opinion as to the frequency of nephritic implication. Albuminuria was quite common, but not as common as in interstitial pneumonia of heart disease. Parkes was nearly right when he said albuminuria might be present in forty-five per cent. of the cases. It was usually most marked at the height of the disease. Dr. Satterthwaite's statistics showed kidney trouble in forty-one per cent. of his cases; in five per cent. of these there was chronic kidney trouble of long standing. In only eight per cent. was it shown, by clinical and post-mortem evidence, that there was no urinary implication. There was, therefore, positive evidence of acute renal disease in thirty-six per cent. of the cases. This percentage was really too low. But we had most to fear in an exacerbation of an old kidney affection.

Little had been added to our knowledge of the clinical aspects of pneumonia since the studies of Laënnec; what had since been done was by Andral, Chomel, Grisolle, Stokes, Williams, Wilson, Fox, and Fagge. In the stage of engorgement we might expect to find dulness, but we do not. Grisolle found in this stage loss of elasticity in the chest-walls, particularly when percussed in the supra- and infra-spinous fossæ. The crepitant râle was regarded by Laënnec as the first pathognomonic sign. It had been compared to blowing up a dry bladder, etc. It was produced by fluid matter passing into the vesicular substance of the lung. Some seasons it was rarely heard. In old people it might be replaced by a coarse crepitant râle. It was now admitted by the best authorities that fine crepitation was also heard in other types of pneumonia, pulmonary phthisis, and syphilis, and even in bronchitis.

Prolonged expiration preceded tubular or bronchial breathing. There might be bronchophony; metallic voice when considerable area of dulness existed. There was rarely any alteration in the symmetry of the si es.

Pain was most frequent in the nipple; next, at the base of the lung, and it might be felt at any part of the chest. It was due to pleurisy. The pulse was usually 100 or more, and might reach 160. Jaundice was not very infrequent, delirium was common, coma occurred in three per cent. of his cases. It was often uræmic. At first the respiration rose from 22 to 36 per minute, but within two days it might reach 40, 50, or 60.

Inflammation of the lower lobe appeared to produce more oppression than inflammation of the upper. In persons with contracted chest and abdominal distention the disease was not well borne.

There was often decided elevation of the temperature in pneumonia. In children it reached a greater height than in adults. It rose one or two degrees at night, and fell in the morning. The highest temperature in his cases

was 108° F.; the lowest, 100.2° F. In ten, the highest average temperature was 104.3° F. The crisis usually occurred between the third and eighth days, and commonly between the fifth and seventh. Unless there were unusual complications or sequelæ, it should not be delayed more than fourteen days at the utmost. The greatest danger was on the sixth day. The immediate cause of death was usually heart failure from prolonged and exhaustive work, or the influence of poisoned blood on the nerve-centres. He had known only two instances in which respiration ceased before the circulation.

As to etiology, Sturges thought it was produced by cold, dry, penetrating winds; but some later writers, as Ziemssen, thought cold an infrequent cause. Twenty-two per cent. of Dr. Satterthwaite's cases were ascribed to exposure to cold. The disease seldom occurred during the warmer months. Occupation had little bearing on the causation. Regarding the influence of micro-organisms, it would be necessary to show that a pure culture inoculated in the blood remote from the lungs would produce lobar pneumonia, but experiments had almost always failed in this respect, and when the lung itself was inoculated lobular, not lobar, pneumonia had commonly resulted.

The pleura was always involved when the inflammation reached the surface of the lung, which almost always occurred. A comparatively frequent complication was pericarditis, developed by extension of the diseased process, or simultaneously. A more important complication was disease of the kidney, to which reference had already been made. The spleen was apt to be enlarged, and there was catarrh of the intestinal tract. True abscess of the lung was rare. It occurred in none of his thirty-six cases of acute pneumonia, but gangrene was noted. He did not believe phthisis could ever develop from acute lobar pneumonia.

As to the mortality of pneumonia, this question had given rise to much dispute, largely because of indefinite statistics. Its discussion, to be of value, must be based on statistics in which were given; 1, the variety; 2, the patient's age; 3, the general character of the attack. At some seasons the fatality was greater than at others, notwithstanding the same general treatment. Statistics before the middle of the present century gave a mortality from fifty-five down to sixteen or ten per cent. Just before the middle of this century, Skoda published statistics going to prove pneumonia was a self-limited disease. About 1842, Fleischmann, a homœopath, gave a mortality of less than six per cent., which set other physicians thinking, and gradually led to less heroic treatment. The fact that the mortality varied in the hands of the same physicians, showed that each case stood by itself. There was evidence, from a study of the statistics, and from the writer's own experience, to show that the expectant plan of treatment was best. We had passed the period when it could be successfully shown that the disease could be arrested. The causes of death showed what should be the direction of treatment. It should not be the reduction of temperature so much as sustaining the heart and obviating renal complications.

Dr. Satterthwaite doubted whether the high temperature in pneumonia was in itself a demon which must be attacked and overthrown. He had been led to believe by post-mortem studies that the use of antipyretics not only weakened the heart's action, but also had some unfavorable action on the kidneys. Every case of acute lobar pneumonia should be treated by itself, and the indications met as they arose. He had often seen benefit from copious repeated cuppings in sthenic cases. In less vigorous persons relief often followed cold water applications. In defective hepatic action relief had come from large doses of mercurials. In weak heart patients had been carried through with alcoholic stimulants. In renal complications marked relief of pulmonary symptoms had followed remedies directed chiefly to the kidneys. Reduction of temperature was best brought about by diaphoresis in preference to antipyretics.

SECONDARY LOBAR PNEUMONIA.

The author then passed to the consideration of secondary lobar pneumonia, a subdivision which had been recognized by the old French school. His views were based upon nineteen of his recorded cases. Without committing himself to an opinion of their etiological value, he had found antecedent conditions as follows: nephritis in 5; alcoholism in 2; phthisis in 2; burns in 2; rheumatism in 1; fracture of the ribs in 1; hypertrophy of the heart in 1; pleurisy with effusion in 1; pericardial effusion in 1. Contemporaneous affections were present as follows: Abdominal dropsy in 1; pericardial effusion in 1; gangrene of the extremities in 1; aneurism of the aorta in 1; bronchitis in 2; syphilis in 2; endocarditis in 2; hydrothorax in 1. Neither phthisical nor syphilitic process had any apparent connection with the secondary lobar pneumonia, and cases in which there was a suspicion of these as a possible cause were thrown out. The general statistics of secondary pneumonia handed down were not reliable.

Secondary pneumonia was usually insidious. Chill was frequently absent, and when present was not severe. Difficulty in breathing might not be marked. The crepitant râle could be heard, as a rule. The temperature rose rapidly as in acute lobar pneumonia, but averaged somewhat lower. With a comparatively high temperature the patient might survive, while with a comparatively low temperature he might succumb. The pulse often rose sharply at the outset, but averaged about 120. Bronchial breathing and dulness might be the most decided symptoms, and in his experience they were the most common. The expectoration was apt to be scanty and afford little help in diagnosis. Renal symptoms were likely to be more prominent than in the acute disease. There was a decided tendency to suppuration. The duration was about the same as in acute pneumonia, but the crisis was likely to come earlier because the patient had been exhausted by the antecedent trouble. The causes of death were about as in acute lobar pneumonia, and indicated the treatment.

DR. H. D. NOYES, First Vice-president, having taken the chair, asked the author if he wished to indicate the line of discussion.

DR. SATTERTHWAITE suggested the question of etiology, also of mortality-rate, and treatment.

DR. A. H. SMITH thought the paper was full of suggestions on a subject which was on every side beset with difficulties. There was one peculiar fact in the history of acute lobar pneumonia which, according to the view we held regarding it, would have a bearing upon the question of etiology. He referred to the temperature, which early reached a high grade, maintained this a considerable length of time, and then abruptly fell. The usual fall on the fifth or sixth day was not only down to normal, but not infrequently below normal, while no corresponding changes occurred in the physical signs to account for it. This fact would seem to indicate that in pneumonia there was something entirely different from an ordinary inflammation. He thought this might have something to do with the formation of poisons in the blood; that at this period the production of these suddenly ceased, if they existed at all. In other words, it seemed to be evidence of a germ influence; whether that germ were the so-called pneumococcus or some other yet undetermined.

The conditions were also very peculiar in another way, with reference to the circulation. It was the pulmonary circulation which was chiefly disturbed; as a result of which there was an accumulation of blood in the venous system, and a paucity on the arterial side. This caused the labor thrown upon the two different sides of the heart to be unequal; that upon the right side being undue in amount, while the left side had less to do than usual. This fact might have its bearing upon treatment directed to the heart. Heart stimulants generally affected the right side no more than the left. Those used in other condi-

tions to facilitate the circulation of the blood by their effect upon the vaso-motor system, would not in this way prove useful in the present class of cases, for it had been shown there were no vaso-motor nerves connected with the pulmonary vessels. The fact that such a variety of methods of treatment had been employed in pneumonia—some being advocated by one class, and others by another, all to be subsequently dropped and others substituted—seemed to show that no very clear indications had yet been discovered. Certainly, however, when the physician observed, as an effect of the obstruction to the flow of blood in the diseased lung, what had been called collateral fluxing, causing, as it were, a drowning of the patient, there was great temptation to do venesection, which was followed so promptly by relief. But this could be of only temporary benefit in this regard, while it might injure the patient in the way of impoverishing his blood.

He agreed with the author that the use of depressing antipyretics was to be avoided, and yet the reduction of the temperature was often a matter of considerable importance. The skin was apt to be active in pneumonia, and when this was true diaphoretics were not indicated. The blood, being surcharged with excrementitious matter, seemed to indicate the necessity for increased diuresis and catharsis. He was not at all surprised that the expectant method had so many advocates, and had perhaps yielded so good results. He would rather do too little than too much in treating pneumonia. In a limited number of cases, the inhalation of oxygen gas would carry the patient over a dangerous point, particularly when there was a large amount of fluid in the other lung. The blood was capable of taking up only a given amount of oxygen, usually no more than what it received from ordinary air, but that slight additional quantity in these cases reduced the labor of respiration to some extent. The heart should be stimulated, but the question of how much alcoholic stimulants were required must be determined in each case. He thought such stimulation was sometimes carried too far.

Dr. Beverley Robinson had never seen the characteristic sputa of lobar pneumonia in any other disease, and when it was present he regarded it as a positive diagnostic sign. Without speaking of the direct cause of pneumonia, he had observed bodily fatigue and foul air to be very efficient factors. It was often seen in persons who had undergone too great mental fatigue, then attended the theatre, and acquired pneumonia in a moment. Treatment, which seemed to be successful some seasons, would be of little benefit at others, a fact which seemed to show that the types of the disease changed. He was heartily in accord with Dr. Satterthwaite in his disapproval of the use of antipyretics, which, while reducing the temperature, also weakened the heart and acted as depressants of the system. In certain cases digitalis in infusion was indicated, and was much safer than the new antipyretics or the two older ones, aconite and veratrin. He was somewhat surprised at Dr. Smith's only limited commendation of the use of oxygen, the value of which he had first become acquainted with through Dr. S. His course of general treatment was the use of oxygen gas, black coffee, simple brandy, or brandy in milk pretty freely employed, avoidance of drafts, the use of small doses of calomel, and judicious use of a cardiac tonic, as strophanthus or digitalis. He deplored the use of the oiled jacket with cotton beneath, which favored cold and thereby extension of the disease.

Dr. Simon Baruch was much interested in treatment. He employed certain heroic remedies, under the directions of a superior medical officer in the army, in the first case he ever treated, and the patient died, he thought in consequence of the treatment. He dropped that method immediately, and in the next two cases tried veratrum viride. In one of these, dangerous depression of the heart took place, and the other patient died. Since that time he had gradually become wedded to the expectant treatment, and the value of this method was learned by a study of the results of the homœopaths at a time when their treatment was what they pretended it was, by infinitesimal doses; that was, really, by allowing nature to take her course, aided only by diet and hygiene. He was not opposed to modern antipyretics, but they were contraindicated in pneumonia, in which disease there was tendency to heart failure, while the temperature was not really an indication of its dangerous character. The proper way to relieve the heart was to divert the venous blood engorging the right side by acting on the portal circulation. Unless the patient were extremely feeble, he would give eight to ten grains of calomel, and if necessary, follow it up with a saline cathartic. Digitalis might also be indicated. He did not think there was change in the type of the disease; that apparent changes from time to time were due to different conditions under which patients were observed. In hospital practice, for instance, subjects were usually nearly moribund when brought in, and the mortality was high. He favored the cotton jacket, and differed from Dr. Robinson in the view that it produced coldness of the surface. On the contrary, raw cotton took up scarcely any water, and when covered with oiled silk the perspiration beneath remained warm and acted as a poultice.

Dr. Robinson added that in his opinion a poultice was decidedly bad, and a jacket of non-absorbent cotton was radically bad also, for if the patient were exposed to the slightest draft it would tend, if cold would cause it, to increase the disease. If cotton were used it should be changed often enough to keep the surface dry. Regarding calomel, better effects on the liver would be obtained through repeated small doses than large doses, which weakened.

Dr. Satterthwaite closed the discussion, and remarked that he was pleased to know the members favored the expectant treatment.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 24, 1888.

Alexander S. Hunter, M.D., President, in the Chair.

A CASE OF CEREBRAL SYPHILIS.

Dr. Ralph L. Parsons had prepared the history of the case for the purpose of emphasizing the importance of early diagnosis and long-continued treatment of syphilis, rather than because of any particular merit in the case itself. The man was forty-five years of age, and gave the following symptoms: His appetite was not good, he slept poorly, his mental and physical condition was depressed, he worried about business affairs, felt stupid, at times was excitable, feared he had softening of the brain. This condition was said to have existed several weeks, and was believed to be due possibly to anxiety about his sick children. He began to have attacks as of fainting, but did not lose consciousness; he would point to the medicine which he wished to take, but would indicate that he could not speak. He lost power to use the tongue freely, and particularly to recall words to express his ideas. The epileptiform attacks grew in frequency and severity, and after three months typical attacks of epilepsy, with convulsion and loss of consciousness, developed, finally assuming the grand mal type, and ending with death. He had never had impure connection, but was reported to have had a suspicious and intractable ulcer on the lip, which, however, finally healed before he came under Dr. Parsons' care. He also had an eruption of the scalp and on the arm. The administration of the iodides appeared to produce marked amelioration of all the symptoms, but it was only temporary. Bichloride was also employed among other measures.

The lesson which the case taught was the probability that thorough treatment instituted at the time of development of the first symptoms would have averted the cerebral affection.

DR. NATHAN S. ROBERTS then read a paper entitled,

THE TREATMENT OF DISEASES OF THE NOSE BY THE GENERAL PRACTITIONER,

in which he called attention more particularly to the nasal affections which it was possible for the general practitioner to treat with success after a moderate amount of training, yet which, if neglected, might prove most distressing locally, or by reflex influence cause asthma, headache, disease of the ear, of the larynx, etc. The skill required in the use of the nasal speculum and rhinoscopic mirror for diagnostic purposes could readily be acquired by any practitioner, and would lead to the use of such means as might be necessary in the removal of polypi, hypertrophied tissue on the turbinated bone, hypertrophic rhinitis, etc. The use of astringents, when not too strong, or too long continued when employed weak, could be safely entrusted in the general practitioner's hand. A cleansing fluid would prove of marked benefit in many distressing cases now left untreated, because the patients hesitated to visit a specialist.

A PLEA FOR THE ACTIVE TREATMENT OF PUERPERAL ENDOMETRITIS BY MEANS OF THE CURETTE.

DR. EGBERT H. GRANDIN opened his paper with some remarks on the extreme conservatism with which physicians regarded novelties in obstetrics, while in certain other departments of medicine, as gynecology, they accepted proposed changes with almost undue haste. Yet every day should add to the knowledge of the obstetrician if he watched his cases carefully, and sooner or later he would become convinced that a part of his earlier conservative training was faulty. Indeed, he might attain to that stage when he would admit that judicious meddlesomeness in midwifery was good. In this spirit he entered upon a plea for a method which, while not strictly novel, did not by any means represent universal practice, and by some might be charged as verging on the meddlesome. After labor the hypertrophied organs had to undergo a retrograde metamorphosis, which took place through a fatty change in the newly formed elements. The cavity of the uterus contained more or less blood-clots, the venous cavities were filled by thrombi, the interior surface resembled a false membrane which had to separate and be expelled. The site of the placenta in particular was rough, jagged, due in great part to thrombi which occluded the sinuses. In brief, the interior of the uterus after delivery resembled a large surgical wound, except that it was physiological. As long as the process remained physiological the vast degenerative and regenerative changes took place without any disturbance of health. But if the normal process were arrested, the elements which were about to be cast off became necrotic. This so-called puerperal degeneration might begin in any part of the endometrium, although it usually started from the placental site and extended until it involved the whole endometrium. During the time taken in the expulsion of the decaying mass the blood might carry a part of it into the system.

Such was a general view of the local pathological phenomena of puerperal endometritis. When the surgeon, after an amputation, found the wounded surface not covered by healthy granulations, he got rid as soon as possible of the offending slough, to obviate its involving deeper tissues and poisoning the system. Nor was he satisfied simply with washing the wound with hot water or sprinkling on of iodoform.

It was not necessary to inquire at present whether the prevailing theory of the origin of puerperal septicæmia was the correct one, namely, that it was due to a germ. It was sufficient for present purposes to state that in the vast majority of instances the septic process was localized at the outset. Hence the necessity for attacking it early, before the lymphatics and the blood-vessels had carried it beyond reach. Fortunately for the woman the symptomatology gave an early clew to puerperal endometritis; yet the obstetrician required for his patient's safety the use of all his senses. Then, again, before the pulse, temperature, general aspect, or change in lochia indicated trouble, the nose would detect beginning decomposition in the lochia. This fact, when existing, should awaken suspicion.

The treatment was prophylactic and local. He would not say that, owing to modern asepsis, puerperal endometritis could always be prevented, but it should be reduced to a minimum. The lying-in woman should be surrounded by a condition of asepsis during and after labor, the uterus should be entirely emptied, and due contraction secured at the end of labor. He would not say that placental remnants or shreds of membrane left in the uterus would necessarily prove a source of asepsis, but they might; and, if the accoucheur was not satisfied of their complete removal, he should resort to such manipulations as would bring them away. Those manipulations should be followed by one uterine douche. If it was a good principle to keep out germs, it was a better one to leave nothing in the uterus which would afford fertile soil for their development. But suppose endometritis had developed, what should be done? He believed the majority of accoucheurs, the world over, were wedded to the intra-uterine douche.

This douching was done with greater or less frequency, according to the notion of the accoucheur, some resorting to it every third hour, some every hour, or second hour, and others at longer intervals, and continuing it perhaps several days.

In mild cases one to three douches might suffice to check the septic process; but, in the majority of instances, it had to be continued with greater or less frequency for days, and occasionally longer than a week; corrosive sublimate was usually employed, $\frac{1}{10000}$ to $\frac{1}{40000}$. Some followed it by introducing an iodoform pencil. Such was a fair statement of ordinary practice.

Some objections to the method were the following: The douche had frequently to be repeated for days, and might then prove inefficient; the antiseptic agent might prove toxic; there might be reintroduction of septic matter. The use of corrosive sublimate had been forbidden in some of the European institutions because of its dangers. Dr. Grandin had not employed it in the intra-uterine douche for two years.

Was there no method which would render unnecessary repeated douchings? It was his belief the dull curette would often replace the douche, and at the same time answer all the indications. The indications were to remove all particles from the uterus which were undergoing decomposition, whether partially loose, partially adherent to the superfices, or extending to the muscularis. Timely action was important; for at the outset the septic process was limited to the cavity of the organ. The dull curette was harmless when used with care, as every instrument should be. The practitioner should be as competent to use it as to use the forceps or the irrigation tube.

As soon as fetor of the lochia appeared, he proceeded to carefully differentiate its source. It was sufficient to state that a thorough vaginal douching with boiled water or antiseptic solution would cause the fetor to disappear in case it were from the vagina. If after a few hours it reappeared, he administered at once an intra-uterine douche, which might entirely remove it if it were due to a loose clot. If it returned, he instituted active treatment; placed the patient in Sims' position, inserted the speculum, fixed the cervix with the tenaculum, introduced the curette bent to the correct degree, thoroughly scraped the interior of the uterus, and gave another douche. Frequently the condition of the patient would so improve within twenty-four hours that she would hardly be recognized.

The fact could not be emphasized too strongly, when the question of danger from the curette was raised; that in cases calling for its use, or that of the douche, the cervical canal was open, and the instrument found its own

way, as it were, into the womb. Still the timid might use the Doléris brush, which entailed no danger. The disturbance of the patient was little greater than during the use of the douche, which latter had frequently to be repeated, and would probably leave a nidus for still further septic absorption.

DR. J. E. JANVRIN thought the paper was eminently practical, and that the points made would meet with the approbation of almost all obstetricians. His own experience in obstetrics had been such that he had never found it necessary to use the curette. He had, however, repeatedly employed the douche, though not for a long time in any one case. He had used it for two or three days at intervals of two or three hours. In many cases of abortion with retention of the after-birth, he had resorted to the dull curette, although septic symptoms may not have set in. The curette was followed by a warm carbolized douche, and there had been no further trouble. He thought the dull curette was harmless in any physician's hands. He had never had toxic symptoms follow the bichloride douche, which he had employed frequently.

DR. A. F. CURRIER did not agree with the author that obstetrics was not a thoroughly progressive science and art, and mentioned improvements which had come to stay, such as Tarnier's treatment of the prematurely born, Sänger's improved Cæsarean section, the primary operation on the ruptured perineum, etc.

Dr. Currier objected to general use of the intra-uterine douche after labor; it was called for exceptionally only. Afterward, if the temperature rose, it should be resorted to. If three or four douches at the most did not prove effectual, he would employ the curette. Recently a prominent young French specialist recommended the use of the curette in all cases after labor. This was going to the extreme.

DR. ROBERT A. MURRAY was quite in accord with Dr. Grandin. If, after thorough cleansing of the vagina, the finger brought in contact with the cervix had a fetid odor it pointed to the uterus as the seat of the trouble. He preceded the curette with the finger, which was better in diagnosis, and gave a sense of the direction of the cavity. Except in abortion it could be introduced without force. In the Maternity Hospital they now saved lives by employing the curette where death not infrequently resulted formerly from continued use of the douche. Pelvic peritonitis, septicæmia, and abscess were aborted by the curette. He saw patients every day in whom removal of the tubes and ovaries seemed necessary, yet their condition might have been avoided by timely use of the curette during a puerperal endometritis. He employed a long curette, the handle being continuous with the head. He preferred to have the patient on the back. If the curetting was effectual the fall in temperature would prove permanent; but if the douche alone were used, and the foreign body were not brought away, there might at first be a fall, but it would be followed by a rise of temperature.

DR. MALCOLM MCLEAN sent a note, stating that he believed in the careful but thorough use of the blunt curette, followed by wiping out the uterus with cotton attached firmly to an applicator, pressed dry after being saturated with a ninety per cent. solution of carbolic acid.

DR. A. M. JACOBUS was in accord with the views expressed in the paper. He preferred the dorsal position during the curetting. In early abortions he used the polyp forceps. If the operation were postponed, the curette would be required.

DR. J. LEE MORRILL said the practice outlined in the paper had been that which he had followed for some time; that was, in cases of sepsis in the puerperal woman he washed out the uterus a number of times, and not being able to reduce the temperature he then resorted to the dull curette. A diagnostic point related to the patency of the internal os. When the lochia became offensive, and he found the internal os open, it was his practice to enter the uterus and clear it of any remaining placenta, membranes, or clots. If he could not wash it out by irrigation or remove it with his finger, he invariably resorted to the curette. He had never had occasion to regret this practice.

Dr. D. P. Austin related a case which showed that he was in accord with the author, while Dr. Messenger, by careful employment of prophylactic measures, had been able to avoid the necessity for the use of the curette. Dr. Grandin closed the discussion.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DISPOSAL OF THE DEAD—THE ABSOLUTE SIGNS OF DEATH—DISCUSSION AT THE MEDICAL AND CHIRURGICAL SOCIETY ON EARLY EXCISION IN TUBERCULAR DISEASE OF THE HIP-JOINT—DOES THE LOCAL USE OF GLYCERINE INCREASE THE VAGINAL SECRETIONS?—A PICTORIAL MUSEUM FOR THE COLLEGE OF SURGEONS.

LONDON, December 17, 1888.

DURING the last few years considerable attention has been directed to the subject of the disposal of the dead. The ordinary methods of burial have long been denounced by sanitarians, who advocate as preferable either "earth-to-earth" burial or cremation, the partisans of the two methods being about equally numerous. The question is one which is beginning to interest the public to no little extent. The fear of living burial is also certainly as active as ever, and, as a safeguard against this, the opinion of an expert is sometimes sought to decide as to death having actually occurred. It is, therefore, not at all surprising that Dr. Richardson's paper at the Medical Society last Monday should have evoked considerable interest. He took for his subject "The Absolute Signs of Death." On two occasions, he said, had he been called in to give a skilled opinion as to the fact of death. He enumerated and discussed the following proofs of death, viz., respiratory failure, cardiac failure, reduction of temperature, rigor mortis, and muscular collapse, coagulation of blood in the veins, putrefactive decomposition, absence of red color in semi-transparent parts viewed with a powerful light, absence of muscular contraction under the stimulus of an electric or galvanic current, absence of a red blotch on the skin after the subcutaneous injection of ammonia, absence of signs of rust (oxidation) on a bright steel needle after plunging it deeply into the tissues.

An important topic was discussed at the last meeting of the Medical and Chirurgical Society, viz., the treatment of tubercular disease of the hip-joint. Mr. Barker read a paper in which he urged that at a certain stage of the disease the complete removal of the tubercular tissue ought to be possible. When treatment by rest had failed he would perform excision. He maintained that in many cases the wound ought to heal by first intention throughout, and often without drainage. He then related a case which he had successfully treated. The patient was a boy, five years of age, who had been under careful treatment for a year. The head of the femur was destroyed and an abscess of the usual kind had formed. Excision was performed, and primary union took place, without drainage, under one dressing. The patient left hospital on the fourteenth day, wearing a double Thomas' splint.

Mr. Bilton Pollard followed with a paper on the same subject, in which he laid down the principle that the wounds necessarily caused by extirpating tubercle from joints would heal as rapidly and as permanently as other wounds of a similar size if certain essential conditions were secured, viz., complete removal of the tubercular growth, perfect asepsis, bleeding checked and the wound made as dry as possible, oozing checked by the even elastic support or a wool dressing and a moderately tight

bandage, absolute rest during the process of healing. Mr. Pollard referred to four cases of advanced hip-joint disease, with caseous abscesses, on which he had operated. In three cases he employed the anterior incision, and in the fourth a curved incision round the upper and posterior part of the trochanter. In none of the cases were drainage-tubes employed. The dressings were changed on the seventh day after the operations, and the wounds were found to have healed by first intention throughout. With the exception of one case, in which the acetabulum was perforated, there had been no recurrence of the disease.

Mr. Croft congratulated the authors of the papers, and said the success of this treatment might be said to mark an epoch in the surgery of the hip-joint. He referred to the practice in vogue seventeen or eighteen years ago. No operations were then performed until the last stage, and the results were disappointing. In 1880 he had given an account to the Clinical Society of forty-five cases in which he had excised the hip-joint, with a mortality of thirty-five per cent. General opinion then was decidedly against early excision, and a committee of the Society reported that it was undesirable to excise the joint unless there was dislocation or sinus. He had continued his own practice of early excision, and since then had had fifty-three operations, with a mortality of only fifteen per cent. These figures caused some misconception to subsequent speakers, and at a later period of the evening Mr. Croft explained that in reference to this mortality of fifteen per cent. he did not mean to say that these deaths had been in consequence of the operation. With one exception these deaths had all been due to tubercular disease at some time subsequent. Mr. Bryant remarked that more evidence was wanted before it could be decided that there must be operation in hip-joint disease at an early stage. He was still in favor of expectant treatment in the great bulk of cases.

Mr. Hulke observed that many cases, if treated with rest in the early stage, would recover without excision, and those which recovered in that way gained stronger limbs and were more fit for work than cases of excision. When cases were spoken of as healing in a few weeks, he supposed the external wound was all that could be referred to, as there would be no complete bony union. He was pleased to hear that Mr. Pollard and Mr. Barker had been able to get out the synovial membrane through an anterior incision; he should have thought it impossible. The operation by anterior incision was no new thing. It was introduced by Hüter, who combined it with a drainage-tube at the back of the joint.

Mr. Howard Marsh said he had never seen such good results as in the cases they had before them. The operations were not quite new; they had all seen a tubercular joint heal quickly after incision. The most important question was not the best way of obtaining primary union, but the ultimate conditions of the limb. The difficult point to decide was what condition could be reached by long rest at first and good nutrition, as compared with early excision. It must be remembered that some evidence was accumulating against the permanence of tubercular disease.

Mr. Keetley referred to a case in which he had excised a diseased hip-joint and scraped out the morbid surrounding tissues. The patient had done very well for six weeks and had then died suddenly from tubercular meningitis. Post mortem, the head of the femur was found firmly joined to the acetabulum, and hardly any trace of cicatricial tissue left. Mr. Keetley said that he regarded the use of the drainage-tube as a safeguard against the mistakes in antiseptic treatment into which we might fall. If all the morbid tissues had not been removed, the drainage-tube would be of use in lessening the chance of self-infection. It did not in the least prevent early convalescence; patients might be up in a fortnight and going about on crutches without being any the worse for a drainage-tube.

Mr. G. A. Wright, of Manchester, then spoke by invitation of the President, and said he had had considerable opportunities for watching the results of hip disease among the tuberculous population of Manchester. Out of the last eight hundred cases he had seen he had performed excision in 135. He thought the best results would be obtained from rest if the cases were taken in time, but the qualifying clause rendered the maxim unpractical. He had never seen better cases than those shown him that evening. He used drainage-tubes himself, and did not get the operation-wounds healed so quickly. The great difficulty was the entire removal of the morbid tissues. He thought tuberculous foci were generally present in the bone, the ligaments, and the synovial membrane, and he had hitherto found himself entirely unable, either by the anterior or the posterior incision, to completely remove these foci. Mr. Wright said he was accustomed, even after excision, to keep on a Thomas' splint for a year, for without it patients were liable to many dangers.

Mr. Makins said that he was at Halle in 1879, and Volkmann was then performing many excisions in cases of early tubercular disease of the hip-joint. In 1887, however, he found that Volkmann had given up the practice in consequence of the ultimate results proving unsatisfactory.

Mr. Barker then replied. He said the first question was, What was early hip disease? He did not wish to excise the joint till he had given up all hope of curing it otherwise; but his case had had rest for a year before the operation, abscesses had formed, and when the joint was laid open it was in advanced disease, and the head of the bone carious throughout. He was in favor of using a Thomas' splint for months after the operation; it had been removed in his case by the boy's parents by mistake.

Mr. Pollard said he considered his cases were progressing toward the third stage; there had been carious bone and abscesses just going to break through the skin. He would not excise if the cases could be got well without.

Does the local use of glycerine increase the amount of secretion poured into the vagina? Many gynecologists aver that it does. Dr. Herman read a paper on the subject at the last meeting of the Obstetrical Society, and as the result of some experiments enunciated the following conclusions, viz.: 1. That when the secretions poured into the vagina are not abundant the local use of glycerine increases them. 2. That when the secretions are already abundant the local use of glycerine does not increase them. In reply to an observation from Dr. Griffith, who said it was important to make sure whether the secretions were formed in the vagina or merely retained in that canal, Dr. Herman said he could not tell whether they were of uterine or of vaginal origin, and he would be obliged if Dr. Griffith could suggest any harmless method of separating the excretions of the uterus from those of the vagina.

The College of Surgeons seem fully alive to the advantages of forming a pictorial museum of disease on the lines suggested by Mr. Hutchinson in his recent Bradshaw lecture. It is announced that they will be glad to receive copies of illustrated monographs, atlases of illustration, and original drawings or proofs of engravings and woodcuts—the latter to be accompanied by references, and, if possible, by description. Adopting a recommendation of the Museum Committee, the Council have also engaged Mr. Burgess, the well-known pathological artist, for a period of three months.

A WORD FOR ICE-WATER, TOO.

To the Editor of The Medical Record.

Sir: Your kind remarks entitled "A Plea for Indigestible Food," encourage me to add a word in regard to drinks. My morning paper contains a prominent review of a popular book, entitled "The Relation of Alimentation and Disease." The author of the book is described as the

"inventor of hot water as a beverage in medicine." The review attributes great injury to the use of ice-water, and a corresponding benefit to be derived from the systematic drinking of hot water during months and years.

In the face of such assertions it is a curious fact that Dr. Dujardin-Beaumetz, when desiring a specimen of gastric juice, first gives to the patient a half glass of cold water. The habit of drinking ice-water before meals is so widely deprecated that it will perhaps be a gratification to some of us to be able to defend it by this eminent example. Cold water apparently stimulates gastric secretion. It does this most probably by dilating the smaller arteries so as to increase the supply of blood. Cold water applied to the skin causes a temporary pallor, rapidly succeeded by flushing and warmth. The dilatation thus obtained is not temporary, but persists for a considerable time. Heat, on the contrary, when applied to the skin, reddens the part temporarily, but finally produces pallor and anæmia. Hot water is better than cold water for the control of hemorrhage, because it produces a final and more lasting contraction of the arteries of the part. Brugio, an Italian, recently observing the brain through the trepanned skull, has found that cold baths produce anæmia, while hot baths produce hyperæmia of this organ.

There is no reason to suppose that heat acts differently upon the mucous membrane of the stomach than it does upon the mucous membrane of the uterus or upon the skin. A hot drink will flush the face as a cold drink never does. The writer has known plethoric people who were obliged to abstain from hot drinks entirely on account of this flushing, and the headache and discomfort which accompanied it. Apoplectic subjects are directed to avoid hot drinks. On the other hand, we administer hot drinks to the patient in a chill because "they drive the blood to the skin," and old-fashioned mothers give hot teas in the eruptive fevers because "they keep the rash out." These instances all point to contraction in the vessels douched by the hot fluid. Pallor of the mucous membrane of the digestive tract undoubtedly follows the use of hot drinks. Hot water sometimes cures dyspepsia, for the reason that in catarrh of the stomach, as in other inflammations, we have unnaturally dilated vessels and sluggish circulation, or even stagnation, of the blood. Contraction is here, as in hyperæmia elsewhere, the first step toward cure. By contraction of the smaller arteries we get a pushing onward of the stagnant venous blood and, in consequence, room for a fresh supply. In catarrh of the stomach, therefore, hot drinks may favor secretion and the better digestion of food.

In the primitive state, however, hot drinks were of course unknown. The animals, in winter, drink from a hole in the ice, and children do not care for hot drinks until they have been taught to use them.

A conclusion to be drawn is, not to introduce children to this practice of a retrograde civilization too early. The child's digestion is not benefited by hot drinks so long as he is in a normal state. Another conclusion is, not to smile superciliously upon your friend because he thinks that a half-glass of ice-water before eating gives him a relish for his food. A third conclusion relates to milk diet. Where milk cannot be taken because it coagulates in lumps, try giving it lukewarm or hot. Ice-cold milk provokes secretion just as ice-cold water does, and this sudden outpouring of the gastric juice coagulates the whole quantity in a mass. By giving the milk hot, on the contrary, secretion is delayed, coagulation occurs more slowly, and a flaky curd is the result. Many people who cannot take cold milk with any comfort, can take hot milk, or milk as it comes from the cow, in large amounts. A fourth conclusion refers to the hot water. While the douching of the digestive tract with hot water may be beneficial for a time, if persisted in after the normal circulatory equilibrium has been reached, it will invariably do harm and may, it is said, even set up a condition of anæmia and atrophy of the stomach—a condition far more serious than the hyperæmia it was intended to combat. It should therefore not be continued for months nor for years, as the popular author before referred to has recommended. As a remedy hot water is not harmless, and its administration should be controlled by the physician's directions just as certainly as the use of drugs.

A last conclusion refers to cerebral hyperæmia. In the condition of flushed face and mental confusion which sometimes results from worry or overwork, try an ice-cream, if it can be digested. If not, try a water-ice, or even a half-glass of the despised ice water. The tranquillizing effect of the cold drink has not yet perhaps received its due share of attention. The possible agency of the hot drink in the production of "American nervousness" is also suggested. It is, perhaps, a significant fact that in the countries with which we are oftenest in this respect compared, chilled wines or malt liquors are more commonly employed. On the other hand, the reviving effect of hot water and other hot drinks in conditions of cerebral anæmia cannot be denied. Any dictum which unqualifyingly says that cold drinks are good, and hot drinks are bad, or that hot drinks are good and cold drinks are bad, must be absurd. Both are good in their place. In the opinion of the writer, however, the cold drink is a physiological requirement, while the hot drink has its place in the treatment of pathological conditions alone.

PROTECTION FOR AMERICAN PHYSICIANS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: You have sounded the proper alarm in an editorial in THE RECORD of December 29, 1888. There is no more flagrant outrage on the medical profession of America than the wholesale emigration of medical mountebanks from the other side of the Atlantic. To my personal knowledge I know not less than six Germans from the "old country," who have not the slightest training in the fundamental principles of medicine, as anatomy, physiology, pathology, or chemistry, but they hang out a "shingle" as Dr. G——,—most of them as Dr. G——, homœopathic, etc.; all doing more or less business, but, as they say, "an Sheeper Blan," from fifty to seventy-five per cent. less than the regular, educated American physician. I am heartily in favor of separating the licensing power from the educational. We need this reform in this as much or more than any State in the Union.

C. E. BEARDSLEY, M.D.

OTTAWA, O.

PROTECTION AND CANADA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial on "Protection for American Physicians" is timely and good. Here, on the Canadian border, the Canadian physicians have a perfect right, as far as the law goes, to infringe on American territory, while we dare not attempt to force collection of a bill contracted "just over the line" one mile away. Nor can we settle there without going through a process, unless we happen to be graduates of one or two especially favored American colleges. But they come over here in droves, and McGill men, judging by their practice, show no more erudition or special ability than we ordinary mortals.

F. L. LADUE, M.D.

ALBURGH SPRINGS, VT.

WAS IT METASTATIC RHEUMATIC PERITONITIS?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Packard's question in your issue of December 29, 1888, reminds me of a case that fell to my lot, in the pre-Adamite days before salicylic acid and hypodermic syringes.

B——, a boy about fifteen years of age, had been engaged, in very raw weather, energetically pursuing the wild duck and other game in the swamps along the Calumet River. He awoke next morning in great pain, with a high fever. I found him suffering with painful swelling of the left elbow, wrist, and finger-joints, and of the right knee. All went well for two days, when every evidence of disease vanished from the extremities, and the entire abdominal region became the seat of most excruciating suffering. The whole belly became tense, distended, and painful. Opiates gave no appreciable relief, though exhibited in quantity sufficient to contract the pupils and to retard respiration. It became necessary to resort to the inhalations of chloroform; but even then the patient could not take enough to keep him from groaning, though in other respects appearing to be completely narcotized. Death occurred after five days of horrible agony. Unfortunately, no autopsy could be obtained.

Several times since then I have seen cases of rheumatism involving the muscular walls of the abdomen, but never anything else that so thoroughly merited the title of rheumatic peritonitis.

HENRY M. LYMAN, M.D.

CHICAGO, ILL., January 1, 1889.

A FATAL CASE OF RHEUMATIC PERITONITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I saw, in the issue of THE MEDICAL RECORD for December 29th, a paper by Dr. Packard describing a case of metastatic rheumatic peritonitis. Dr. Packard has never, he says, seen a fatal case. I have seen one. The case was as follows: I was called as consultant with a gentleman, some years ago, to see a lady who had been delivered by him ten days previously. The medical gentleman, whose name I cannot unfortunately remember, gave the following history: The patient did well until the fourth day, when she was seized with a severe attack of acute rheumatism in both wrists. The seizure invaded almost all the joints until, finally, two days before I saw her, she developed acute peritonitis, the joints becoming much better. In spite of all the doctor could do, the patient died a day or so after I saw her. There were no signs of any septic trouble due to the confinement—the lochia being at all time sweet and free, the womb itself free from tenderness, no chills, etc. The doctor reported the case, but I have forgotten where it was published.

Truly yours,

MARTIN BURKE, M.D.

147 LEXINGTON AVENUE.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 30, 1888, to January 5, 1889.

WATERS, WILLIAM E., Major and Surgeon. Leave of absence granted in S. O., 129, November 9, 1888, Department of the Columbia, is extended one month. Par. 9, S. O. 2, A. G. O., January 3, 1889.

AINSWORTH, FRED. C., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, to proceed to New York City, N. Y., and Brooklyn, N. Y., on business connected with the Medical Department. Par 20, S. O. 302, A. G. O., Washington, December 29 1888.

FECUNDITY AND AGE.—A woman in Edinburgh, Scotland, is reported pregnant at the age of sixty-two, it being her twenty-third time. She was also pregnant at the ages of forty-seven, forty-nine, fifty-one, fifty-three, fifty-six, and sixty.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 5, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	19	8
Scarlet fever	274	43
Cerebro-spinal meningitis	5	4
Measles	477	27
Diphtheria	169	46
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

TREATMENT OF FETID DIARRHŒA.—The following formulæ are suggested in the *Bulletin Médical* for this condition:

℞. Bismuthi salicylat.,
Magnesiæ calcinat.,
Cretæ præparat.,
Calcis phosphat. ..... āā 3 ijss.
M. Rub to a smooth powder.
M. DOSE.—Half a teaspoonful taken daily.

Also give an enema of:

℞. Bismuth. salicylat. ..... 3 ijss.
Acid. salicylic ..... gr. xv.
Aquæ bullient. ..... f ʒ v.
M. To which add a strengthening diet.

Another plan of treatment is the following:

℞. Naphthalin. pur.,
Sacchari ..... āā 3 j.—gr. xv.
Essent. bergamot. ..... gtt. i.–ij.
M. Rub to a smooth powder and divide into twenty powders, of which take one every hour.

Use with this also the following enema:

℞. Naphthol ..... gr. xxx.
Alcohol ..... f ʒ jss.
Dissolve, and add of distilled or boiled water a pint.

Formulæ for injection brou.

℞. Opii,
Catechu. ..... āā gr. vjiss.
Crooi. ..... gr. xv.
Aquæ,
Fiat liq. q. s. ad. ..... f ʒ ij. f ʒ ij.
et adde
Plumbi subacet. ..... gr. xxijss.
Zinci sulphat. ..... gr. xlv.

POISONING BY OIL OF SASSAFRAS.—Dr. Albright reports this case in the *Cincinnati Lancet-Clinic*, December 8, 1888: A German, aged eighteen years, took by mistake a teaspoonful of oil of sassafras and went to the barn to work. He noticed in a few minutes strange feelings about the head. In half an hour hallucinations (declared he was in heaven) and occasional vomiting. Half hour later unconscious; vomiting continued when disturbed or on any exertion, followed by great prostration and relaxation. Two hours after taking, the extremities cold; radial pulse detected with difficulty. Continued in this way until about 6 P.M., the drug having been taken at 2 P.M. At this time the doctor found him with pupils somewhat dilated; pulse at wrist barely perceptible; respiration twelve per minute; extremities cold. Could be roused with difficulty, but incapable of comprehending or answering questions or of recognizing anyone. On attempting to administer some egg albumen he vomited again. The writer could detect barely a trace of the odor of the oil, and concluded it was mostly ejected from the stomach. The vomited matter contained abundance of very tenacious mucus. Concluding that the violence of the storm had passed, he was ordered quiet, with heat to extremities, and stimulants. He regained complete consciousness by midnight, and was ready for breakfast in the morning, and with the exception of feeling a "little weak" made no further complaint.

THE MENOPAUSE IN SOME OF ITS RELATIONS TO DISEASE.[1]

BY JAMES B. HUNTER, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK.

THE menopause is an event in the life of woman interesting alike to the general practitioner and the gynecologist. It is an event which may be said to occupy a place on the border line between the physiological and pathological processes, passing readily from one to the other. The purpose of this paper is to consider very briefly some of the variations from the normal type of the event known as the "change of life," and to point out the danger of overlooking diseased conditions when they happen to be coincident or complicated with that change. The subject is rendered somewhat difficult to treat concisely from the wide difference that exists in regard to the age at which the menopause occurs, and the manner in which it is heralded and established.

As to the age at which it occurs, there is a difference of many years; but, as a rule, it takes place between forty-five and fifty. In exceptional cases it may occur as early as twenty-five, or later than sixty, without evidence of any appreciable disease, and without any disturbance to the general health. Such exceptions are so rare that any marked peculiarity as to age should excite suspicion and inquiry, especially if accompanied by any distressing or alarming symptoms. It may be remarked in passing, that whereas there is a wide range of difference in the age at which senility occurs, there is a very limited and narrow range of difference in the age at which puberty declares itself—and that also may be regarded as a "change of life"—the only change which can be compared or contrasted with the one under consideration, the one being a process of evolution, the other one of involution.

The menopause may occur early from the following among other causes: 1, Heredity; 2, anæmia; 3, excessive child-bearing; 4, superinvolution of the uterus; 5, ovarian disease or disease of the tubes; 6, shock or other psychical cause.

The menopause may be delayed beyond the average age by the following causes: 1, Heredity; 2, the hemorrhagic diathesis; 3, cardiac disease; 4, subinvolution; 5, fibromata of the uterus; 6, sexual excess; 7, metritis or endometritis; 8, chronic displacement of the uterus; 9, ovarian disease; 10, plethora; 11, intra-uterine growths.

It is necessary to distinguish between uterine hemorrhage or flow—which may occur from many other causes besides those mentioned—and the regular recurrence of the menstrual discharge. The climacteric is not merely a local change, but something more. It means a profound general constitutional revolution. Among the local changes which take place may be noted:

1. The atrophy and growth of fibrous tissue in the stroma of the ovaries, at the expense of the Graafian vesicles.

2. Atrophic change in the mucous membrane and glands of the uterus, with increase in fibrous tissue.

3. Atrophy of the vagina and external genitals.

4. Diminished blood-supply of the pelvic organs.

[1] A paper read at a meeting of the Practitioners' Society, December 7, 1888.

Preceding these changes, as a sort of rebellion against their approach, there is often an exaggeration of all the normal conditions, with increased vascularity and corresponding nervous phenomena. At this period there is an undue strain on all the pelvic organs, and latent diseases often receive a stimulus that declares itself in unwonted symptoms. This is the period when neglected lacerations of the cervix uteri are apt to become evident. It is the period when malignant diseases of the pelvic organs often develop, or, if previously existing, assume an aggravated form, and take on a rapid growth. It is the period at which hereditary traits, especially insanity, are prone to appear. There is a general impression that Bright's disease—diabetes—and many other diseases are more liable to occur at this time than at any other; and hence, probably, the popular dread among women of the "change," as of a dangerous river to be crossed in the journey of life.

The preliminary period spoken of may be either brief or long. In some women it occurs as a warning, after which normal menstruation is restored for a time, perhaps for many months, when the warning again returns. These oscillations may be repeated several times. The preliminary period is one of heightened arterial tension and marked disturbance of the circulation. The condition may be observed and studied well in the cases, now perhaps too common, when the menopause is established prematurely by the removal of the ovaries and tubes. One of the symptoms almost always present, often for a year or more after operation, is the frequent painful flushing of the face, which occurs sometimes several times a day, sometimes accompanied by a slight vertigo.

The local disorders due to the approach of the menopause are of exceeding practical interest. It is not always easy, it is sometimes impossible, to distinguish between the symptoms due to this cause and those due to causes entirely independent of age. In one case it may be prudent to interfere as little as possible; in the other, active interference may be imperatively demanded. The history of the patient and the nature of the symptoms will decide as to the necessity for a physical examination, which will often make the diagnosis easy. Where the symptoms are not urgent, time will often clear up all difficulties. The symptoms most likely to be present in doubtful cases are:

HEMORRHAGE.—This is always alarming if severe or long continued, and may be due to so many causes that it is often perplexing in the extreme. Cases occur to which not even the most careful physical examination will give the slightest clue, if the congestion of the menopause is not taken into account. Due weight must be given to the fact that a patient may be suffering from disorders attributable to her age, *plus* some organic disease. Uterine fibroids are a common cause of hemorrhage and of menorrhagia, and although after the menopause this class of tumors usually give little trouble, it must not be forgotten that they may postpone the change for several years, and often do so. Of this fact we have abundant clinical evidence in subjects of fibroid tumors who are advised to wait for the "change of life" in order to avoid surgical interference. Women who would otherwise probably cease to menstruate at forty-five often continue to flow till fifty, when there is a large fibroma attached to the uterus. I have seen several cases where the existence of a fibroid tumor for years caused no menorrhagia until the age when the menopause should take place. In women

whose menstruation has been regular and not excessive, a marked increase in the flow, coming on after forty, and persisting for several months, is always to be regarded with suspicion, especially if the discharge has become more watery, has an offensive odor, and is complained of as acrid and irritating. In such cases no time should be lost in making a physical examination. Epithelioma of the cervix, which may have been progressing slowly for many months, without any symptoms, often receives a sudden stimulus at the advent of the menopause, and is first discovered only after it has made astonishing progress. It is a grave error, in the presence of the symptoms described, and at the critical age, to trust to nature and time for relief. The rapidity of growth of which cancer of the cervix uteri is capable at that period of life is almost incredible, and justifies the use of every means to make a positive and early diagnosis.

Hemorrhage caused by a small pediculated polypus within the uterus may easily be mistaken for that due to a sloughing cancer of the cervix, even the odor resembling that of cancer. Such polypi often hang by a slender pedicle and become fixed in the canal of the cervix, the exposed portion breaking down, and having almost exactly the appearance of a malignant growth. A menorrhagia which occurs with comparative regularity every month, and which is limited in time, is less to be dreaded than a flow, even slight, that lasts the greater part of the month. There is a rare form of senile metritis which is accompanied by a constant oozing, and often by pruritus vulvæ, which simulates very nearly the flow that takes place in either cancer or sarcoma of the body of the uterus, but it has not usually the offensive odor of the discharge in malignant disease. A form of bleeding in which the discharge is dark and tarry, sometimes alternating with discharges of offensive pus, usually signifies degenerative changes in the tubes and ovaries. A flow of bright red blood, occurring in gushes, may signify ulcerative lesions of the endometrium, to which there is a greater liability near the menopause than at any other time.

Closely allied to hemorrhages are the various discharges from the vagina which occur toward the close of the menstrual age. The serous flow, often profuse, in cases of epithelioma of the cervix, is a marked feature of that disease, which may run its entire course without the occurrence of any hemorrhage whatever. A somewhat similar watery discharge sometimes occurs from the cavity of the uterus in senile endometritis, and may cause an error in diagnosis if physical examination is neglected. A watery or sanious discharge, caused by an intra-uterine polypus or fibroid tumor, may simulate the discharge of epithelioma so closely as to render diagnosis impossible without dilatation and exploration of the uterus. That procedure is to be recommended in every doubtful case. One point I wish to emphasize is the greater necessity for careful, thorough examination at the critical period of life than at any other period, because of the rapidity with which changes then take place, when there is a temporary stimulus to the circulation and a deranged condition of the nervous system.

Nervous and Other Symptoms. — For the same reason, because it is the *temps critique*, I believe that greater, and not less, attention should be given to all nervous and other symptoms, which are too often ascribed simply to hysteria. Melancholia, profound depression, the disposition to exaggerate the every-day cares of life, should be watched with care and sympathy, especially if there is any trace of insanity in the family history. The morbid dread of cancer, from which so many women suffer all their lives, is particularly active at this period, and the subjective uterine symptoms often give some ground for apprehension. Such fears can best be allayed by making sure that there is no real cause for alarm.

Pain is not commonly a prominent feature in the disorders of the menopause, but in cases of previous pelvic peritonitis, with adhesions, very severe pain is often experienced during the congestive period. Pain from this cause may be expected to disappear when the menopause is fully established.

I have endeavored to show that the most serious period in a woman's life is that preceding the establishment of the menopause, and would again express the opinion that while the menopause has its own decided influence on the mental and physical health, and has its own train of symptoms and disorders, that the radical and profound change which it implies includes and influences all other diseases to which she is liable at that period of her life.

My attention has been directed to this subject quite recently by the care of two cases, neither of which had been suspected of anything more than the irregularity commonly ascribed to the approach of the climacteric. One patient proved on examination to have a well-developed sarcoma of the body of the uterus, and was treated by extirpation of the entire organ by the vagina. She made a good recovery. The other case had such slight symptoms that no examination had been thought necessary until, when she came under my notice, the vagina was found literally filled by a cauliflower growth originating on the cervix. This experience is not unique. On the contrary, it is lamentably common. By far the larger number of cases of cancer of the uterus that present themselves at the New York Cancer Hospital are subjects of disease too far advanced for anything more than palliative treatment. Many of them have not even suspected the existence of any serious disease until it was too late to hope for cure. Yet their history, in many cases, is clear enough as to the existence of symptoms that, had they occurred at an earlier age, would have been promptly recognized. While, therefore, early recognition of cancer is at all times of the utmost importance in regard to treatment, it is especially so at the period when the menstrual life is drawing to a close, when the dangers of malignancy are aggravated, and when the rate of growth of all forms of cancer is enormously increased.

ECLAMPSIA INFANTUM IN ITS RELATION TO FEVER.[1]

By HENRY W. BERG, M.D.,

NEW YORK.

The comparative importance of a disease, from a practical therapeutic stand-point, lies not in its rarity but in its frequency. While a rare affection may attract curiosity and thus gain interest, the common affections of every-day occurrence compel the deepest inquiry. Remembering this, I do not consider it necessary to offer an apology for presenting to your attention a very ordinary condition, but yet one which, from the frequency of its occurrence, necessitates the most thorough understanding of all the factors which enter into its etiology, the pathological conditions under which it occurs, and the most logical and effectual means of treating it. When it is remembered that of all the direct causes of death in infant life, eclampsia, under one form or another, is the most frequent, it will appear that the importance of the condition is not over-estimated.

Eclampsia is not in itself a disease, it is a symptom. Nothnagel[2] and other authorities discuss the possibility of its occurrence as an idiopathic affection. Ozanam[3] limits the term to convulsions which are not dependent upon the presence of any other disease or condition. Convulsions occurring at the outset, or in the course of acute infectious diseases, inflammations, etc., Nothnagel terms epileptiform. Eclampsia[4] infantum should be considered not so much a disease as a symptom. In one case the convulsion may precede or usher in a pneumonia,

[4] Berg: Art. Eclampsia, in Wood's Reference Handbook of the Medical Sciences.

in another it may appear at the same time with a brilliant scarlatina; here dentition appears to have been the exciting cause, there the ingestion of indigestible food; in all of these conditions the attacks resemble each other, although in each case the clinical etiology is different. Looking, then, upon eclampsia from an etiological standpoint, it appears that all the possible conditions under which eclamptic attacks may occur in children will come under one of the following subdivisions:

1. Febrile or symptomatic eclampsia.
2. Reflex eclampsia.
3. Toxic eclampsia.

We shall devote our attention mainly to the consideration of the febrile form of eclampsia, although it must not be forgotten that a particular case of eclampsia may be toxic or reflex in its character, and yet fever may be one of the important concomitant symptoms.

At the outset, or in the course of inflammatory conditions, as well as in the acute infectious diseases accompanied by increased pyrexia, eclamptic convulsions occur—rarely in adults and older children, frequently in very young children and infants. In these cases the fever has been almost uniformly supposed to be the cause of the convulsions. A little consideration, however, will show that we have no logical right to assume that the convulsion is the result of the increased temperature, simply because the two symptoms occur so frequently together. Further evidence of the correlation of these two symptoms is certainly necessary, for many diseases which are not accompanied by fever have eclamptic attacks occurring in their course. But even if we grant that the eclamptic convulsions are the direct result of the fever, it does not follow that they are caused by the elevated temperature, but may possibly depend upon toxic changes produced in the blood or nerve-centres as the result of the fever, or as one of the manifestations of the poison of the general disease.

The classification of eclampsia which I have given above I have quoted from an article on this subject which I contributed to Wood's "Reference Handbook of the Medical Sciences." It shows that I do not attempt to assign any one cause, or series of causes, for the affection. On the contrary, it is a symptom of a vast number of affections, and it would be almost as futile to attempt to give all of the conditions which produce pain, as to enumerate all of the conditions in which eclampsia may figure. That many cases are toxæmic is undoubtedly true; that reflex eclamptic attacks occur is without question. It is our purpose here to establish upon a physiological basis the fact that the eclampsia which occurs in the course or at the outset of febrile diseases, in other words, the most frequent form of eclampsia occurring in children, is dependent upon high temperature, and is the direct result of the elevated temperature upon the nerve-centres.

Convulsions, both eclamptic and epileptic in character, although studied with much interest in all times, have been understood, even to a limited extent, only in recent years. About 1850 there simultaneously arose in different portions of the medical world a special interest in the study of convulsions, particularly as regards epilepsy. While, on the one hand, experimental physiological investigations were undertaken by brilliant observers, resulting in the artificial production of convulsions in the lower animals after various lesions, others, equally competent, studied the central nervous systems of epileptics upon the post-mortem table, with the purpose of establishing the lesion or lesions productive of chronic epilepsy. A third series of writers, availing themselves of the progress made in the knowledge of the physiology of the nervous system, advanced theoretical reasons why one portion of the nervous system, rather than another, must be the seat of the pathological cause of the disease.

It will readily appear that the experimental epilepsies, or rather, convulsions, produced on animals by the first series of investigators to whom I have referred, were not really epileptic, but rather epileptiform, or eclamptic. The results of these investigations, and they are by far the most important, can be applied to the study of eclampsia even more legitimately than to the study of epilepsy. We find, then, that Kussmaul and Tenner,[1] in 1856, conducted a brilliant series of experiments upon rabbits, in which they demonstrated that by cutting off the blood-supply from the brain and medulla oblongata of rabbits, by means of temporary ligatures passed around the four large arteries providing the brain (the carotids and vertebrals), eclamptic convulsions severe in character were produced; as soon as the ligatures were loosened the convulsions ceased. It was found, moreover, that after the removal of the hemispheres and cerebellum the convulsions were still produced by tying the blood-vessels, and thence the conclusion that anæmia (followed by venous hyperæmia) of the medulla was the cause of the convulsions. The cutting off of venous return (by tying the large veins) resulted in similar convulsions, and allowing the animals to bleed to death, by severing the arteries or veins, had a similar effect. Brown-Séquard,[2] in a series of articles contributed in 1856 and 1857, produced convulsions by section of different portions of the cord, particularly in the lumbar region. He found also (in guinea-pigs) that section of the sciatic nerves would produce convulsions, and what is more important, the progeny of such animals were often found to be subject to epilepsies. In such animals he was able to mark out certain epileptic zones—markedly, for instance, the distribution of the fifth nerve, the irritation of which was sufficient to produce a convulsion. Many of his so-called spinal epilepsies, however, were afterward shown to be mere reflex manifestations, the result of the irritation, and not convulsive in character. Later, Nothnagel, by irritation and section of the medulla of guinea-pigs caused convulsive seizures; and recently Dr. Otto Binswanger,[3] has repeated the experiments of Kussmaul and Tenner, as well as those of Nothnagel, and has reached conclusions identical with those of Nothnagel, namely, that the medulla is the proper starting-point of convulsive seizures.

Post-mortem finding in chronic epileptics have shed no light upon the etiology of convulsions. But the third class of investigators to whom I have referred above have been successful in applying the knowledge obtained by experimental physiology of the central nervous system, and have done more to elucidate this subject than even the practical investigators already referred to. Among the most valuable monographs in this direction is that of Schroeder van der Kolk,[4] who, writing shortly before the experiments of Kussmaul and Tenner, ascribed epileptic seizures to an exaggerated excitability of the medulla oblongata. Here, he reasoned, was the central point at which all motor tracts converged on their paths into the spinal cord; here were the nuclei for the pneumogastric, hypoglossus, spinal accessory, and glosso-pharyngeal nerves—the nerves providing the muscles of the tongue, face, pharynx, larynx, respiratory apparatus, and the motor nerves of the extremities. An irritation or lesion here would affect all of these muscles, as is the case in a complete epileptiform spasm.

Reynolds[5] states the views of Schroeder van der Kolk with admirable clearness in his article on "Epilepsy." "The derangement which leads to an epileptic (or eclamptic) attack consists in an increased and perverted readiness of action of the medulla and vaso-motor system of nerves, the result of such action being the induction of spasm in the contractile fibres of the vessels supplying the brain, and in those of the muscles of the face, pharynx, larynx, respiratory apparatus, and limbs generally. By

contraction of the vessels the brain is deprived of blood, and consciousness is arrested. The face is, or may be, deprived of blood, and there is pallor. By contraction of the muscles which have been mentioned there is arrest of respiration, the chest-walls are fixed, and the other phenomena of the first stage of the attack are brought about." "The arrest of breathing leads to the special convulsions of asphyxia, and the amount of these is in direct proportion to the perfection and continuance of the asphyxia." In young children the nervous system is especially in a condition of what may be termed unstable equilibrium, the motor functions being imperfectly developed; this excess of irritability is especially marked in the medulla oblongata. Hence the proneness of young children to eclamptic attacks is easily accounted for. But although van der Kolk's paper was written long before the localization studies, in 1870, of Fritch and Hitzig and their followers, yet he did not even then believe convulsive seizures to be primarily dependent for their origin upon lesion of the medulla alone, but recognized that a primary irritation of any portion of the nervous system, particularly of the cerebral cortex, might excite, secondarily, the convulsive centre in the medulla, and thus produce a more or less perfect epileptiform spasm.

The works of Hughlings Jackson [1] have shed more light upon the method of the production of epilepsies, particularly of the localized epilepsies, than those of any other observer. He taught the importance of studying the attack in each individual case, with especial reference to the aura and onset, with a view to localizing the "discharging lesion." He distinguished between discharging and destructive lesions, the one resulting in irritation phenomena, such as convulsions, the other resulting in paralysis. He taught the importance of localizing those that produce the former, as well as those that produce the latter. There is nothing, however, in his views which militates against the action of the medulla as a convulsive centre. The local discharge of nerve-force simply sets in motion the series of phenomena which result in a convulsive seizure.

This rapid *résumé* of the pathogenesis of convulsive seizures has had for its object chiefly to recall the fact that the chief seat of disturbance in the nervous centres, resulting in an epileptiform or eclamptic spasm, is at the medulla oblongata. If elevated temperature has a direct action in the production of eclampsia, it is upon this portion of the nervous system that its effects must be sought. Fever itself is a nervous phenomenon, the effect of a primary derangement of the nervous system. This much —and it is an important step in advance—the investigations of the last few years have demonstrated. No more interesting study has occupied physiologists of the last decade than those concerned with the pathology of fever. Dr. Macalister,[2] in one of his Gulstonian lectures, gives an admirable *résumé* of the subject. Dr. Welch,[3] in his Cartwright lectures, delivered in this city, has made the subject popular with the medical public. It is far from our purpose, however instructive it might be, to enter upon a discussion of the pathology of fever; but I shall mention certain points, which are now well established, that will throw some light upon the febrile process in its relation to eclampsia.

Two functions are going on simultaneously in the normal living body, which are complementary to each other. They are heat-production, or thermogenesis, and heat-dispersion, or thermolysis. These complementary functions are so proportioned to each other that the healthy body maintains an even blood temperature under various conditions of activity, external temperature, digestion, etc. Now, theoretically, fever might be the result of excessive thermogenesis or diminished thermolysis, or both of these combined; or, finally, it might be the result of increased thermogenesis with increased thermolysis, but the former relatively greater than the latter. Experiment has shown that increased thermogenesis is always present in fever. Not only is the temperature of the body raised, but there is a real increase in the production of heat. It is also found, as a matter of experiment, that there is an increase in the amount of heat given off from the body, or increased thermolysis. It is evident, *a priori*, that the increase in the heat-production must be greater than the increase in the heat-loss, for if it were not, the body temperature would not be increased. Normal temperature, then, is dependent upon the maintenance of a proper proportion between heat-loss and heat-production. The mechanism which controls this proportion resides in the central nervous system. In fever this mechanism is disturbed. Experimenters have sought to localize the portion or portions of the nervous system in which this mechanism resides, and although this work has been prosecuted only in recent years we have already a considerable literature upon the subject. Wood, Liebermeister,[1] Leyden,[2] Ott,[3] Aronson and Sachs,[4] Rosenthal, and others, have done magnificent work. Wood found that in making a partial section through the fissure at the junction of the medulla and the pons, in the dog, the thermogenetic function is stimulated and heat-production is augmented. Irritation of the same region of the medulla by a puncture resulted in a marked temporary fall in the rate of heat-production. He supposed, therefore, that through this region there passed fibres which exerted over the heat function an effect similar to that of the pneumogastric over the heart, namely, an inhibitory action—section or paralysis resulting in heat elevation, while an irritation causes heat-depression. Later observations do not confirm these views. They serve to show, however, that a large tract of nerve-fibres, corresponding proximately to the motor tract, exists in the medulla, which carries the potency of heat-production. Aronson and Sachs, in an admirable series of observations, found that when a fine needle is passed vertically through the brain of a rabbit, in such a manner as to puncture the fibres to the medial side of the corpus striatum, the temperature of the muscles and rectum rises from one and one-half to four and one-half degrees F., and remains for several hours. This experiment can be repeated in different animals with almost constant results; thus the thermogenic tract, which at the medulla corresponded to the motor tract, has separated from it, passing to the inside of the corpus striatum (nucleus caudatus), while the motor fibres are continued onward to the cortex through the internal capsule.

Ott, in observations contributed to the *Journal of Nervous and Mental Diseases*, April, 1884, claims to have discovered four cerebral heat-centres.

1. At the anterior inner extremity of the optic thalamus.
2. At about the body of the corpus striatum.
3. At the caudate nucleus.
4. Near the median line, between the corpus striatum and optic thalamus.

He finds that the first-mentioned of these centres, when punctured, produces the greatest and most marked rise of temperature. Although much work must yet be done before we shall know as much of the localization of heat-centres, so called, as we do of motor areas, or of the origin, course, and distribution of thermic nerve-tracts, yet this much has certainly been established, that the heat function of the body is under the control of the large nervous centres, chiefly located in the brain, and probably distinct from the motor centres. For the thermic nerve-

tracts, although separate in the brain from the motor nerve-tracts, are closely connected with the latter at the medulla oblongata.

It would appear, then, that an attack of eclampsia occurring in the course or at the outset of a disease or condition of which the temperature is, apparently, the causative element, as far as the convulsion is concerned, calls into activity two sets of nerve-centres—the thermogenic centre or centres, and the convulsive centre or centres.

Hughlings Jackson has shown that what he calls a "discharging lesion" of any portion of the brain may cause the action of the medulla as a convulsive centre. We do not know the nature of such a "discharging lesion;" it leaves no trace which can be demonstrated at the post-mortem table. It may be excessive hyperæmia, or anæmia, or some minute change in structure. We have no means at present of demonstrating the lesion. A similar alteration or lesion occurs in the thermogenic centre. Its effect is fever or rise of temperature; secondarily it throws into activity the unstable convulsive centre, if I may so term it, in the medulla, especially in infants, in whom, as has been seen, the medulla, together with the motor centres, are in an exalted state of irritation. Furthermore, it is probable that in the medulla the motor and thermic nerves are intermingled. What more natural than that an irritation of the one results in an irritation of the other? Of the probability of this hypothesis we have, however, another proof. The same reasons that would lead us to expect that the irritation of the fever-centres should, in proper subjects, cause an irritation of the convulsive centre would also presuppose the possibility of a reversal of this process. In other words, we should expect the activity of the convulsive centre to produce a secondary activity of the fever-centre.

This is certainly fully demonstrated by practical experience at the bedside.

All authorities are agreed as to the enormous rise of temperature which occurs in the course of a so-called "status epilepticus." The epileptic falls into convulsions, repeated at very short intervals, so that the patient does not recover consciousness for hours, or even days. Shortly after this condition has set in the temperature begins to rise, and sometimes reaches an enormous height. Bourneville has seen it as high as 107½° F.; Reynolds reports equally high temperatures.

I am convinced that such a temperature can only be accounted for upon the hypothesis that the irritation of the eclamptic centre has been reflected to the thermogenic centre. For in "status" the convulsive movements are sometimes so slight as to be scarcely perceptible, the patient is unconscious, and perhaps foams at the mouth, the eyelids are open, the eyeballs rolled up and toward one side; but certainly the rise of temperature cannot be accounted for by excessive muscular activity. This quiet form of "status" can be seen in children suffering from reflex eclampsia without fever at the outset. If seen, however, when the little patient has been unconscious and slightly convulsive for hours, the temperature will be seen gradually to rise. In these cases the increased activity of the heart's action is not in proportion to the rise of temperature. The urine, if examined, will be found normal, and the only way in which I can explain this secondary rise of temperature is on the hypothesis I have just stated; and here we have an important indication for treatment. In these cases of eclamptic or epileptic "status" with secondary rise of temperature reduce the fever, both to guard the patient from the effects of high temperature, but above all from the reflexion of the irritation of the thermogenic centre to the convulsive centres, the irritation of the one causing the irritation of the other, and *vice versa*.

The chief object of these remarks is a therapeutic one. I find in general practice that a great deal of importance is attached, both by physicians and even teachers and text-books, to the administration of antispasmodics in eclampsia, particularly in eclampsia infantum, while very little attention is given to the cause of the convulsion. While in toxic eclampsia, as in the nephritis of scarlet fever, the toxic element is treated, the fever is overlooked. Where an inflammatory disease is diagnosticated with eclampsia, the fever is treated, not in the energetic way which is necessary, if we recognized it as a direct cause of the eclampsia, but as a symptom of the inflammation which it is desirable to get rid of. In reflex eclampsia, such as that due to dentition, he who believes in such an eclampsia will scarify the gums, and the fever, if present, will be overlooked. I do not wish to be understood as claiming that every case of eclampsia is accompanied by fever, even if toxic or reflex. On the contrary, I have tried to be careful to give no such impression. In many cases the eclamptic centre is primarily excited, and if the eclampsia does not last too long fever does not occur; but it is certainly true that eighty per cent. of the cases of eclampsia met in practice are accompanied by fever. The thermometer should first be questioned before any form of treatment is entered upon. If there is a temperature above 102° reduce that, and omit the antispasmodics if you will, and, as a rule, the patient will do well. In other words, I believe that an attack of eclampsia infantum should be treated as a symptom, the cause of which, as a rule, is fever, unless it is proved to be otherwise. Upon this basis I have treated my cases, within the last two years especially, and have had gratifying results. As a rule, the eclampsia ceases when the temperature has been reduced to the normal. In inveterate cases of "status," where the temperature has risen as a result of the continued spasm, attention to the temperature often succeeds in cutting short an attack which appeared hopeless. In the article on "Eclampsia Infantum" in Wood's "Handbook," I have advised the use of antipyrine and antifebrine, together with cold or tepid sponging, as may be necessary, with equal parts of water and alcohol. The former are given to clinch the more rapid effect of the latter. The thermometer should be the guide. Whatever else is done in febrile eclampsia may or may not be useful. The reduction of fever is peremptory.

In treating my cases upon the above basis I have been so successful within the past few years that I may be pardoned if I give my method of treatment in detail. Upon being called to such a case I first take the temperature; finding this elevated I examine the patient thoroughly for a cause of the elevation. Having arrived at a diagnosis, I proceed to reduce the fever in the following manner: If the temperature be above 103°, I prepare a mixture of one part of alcohol to three parts of cold water, from which the nurse wrings perfectly dry a sheet large enough to be wound around the little patient in a double layer. Over this enveloping sheet is wrapped a perfectly dry blanket. In the meantime a proper dose of antipyrine or antifebrine is administered by the mouth, if the patient is able to swallow; by the rectum in double doses if unable to swallow. Such a dose is repeated within a half hour, and if the temperature is very high a third dose is given. I am accustomed to give children a year old six grains of antipyrine, repeated three times; to children over two years of age, eight grains, repeated three times. Antifebrine is effective in about half the quantity. The cold sheets are changed at first at frequent intervals, sometimes every five minutes, later on at longer and longer intervals, until the temperature having fallen to the normal they can be dispensed with entirely. On general principles I allow an enema to be administered, and have an ice-bag applied to the head. The bromides I rarely consider necessary in a case of true febrile eclampsia. In cases of "status" with no rise of temperature, we have no other means of treating the patient except symptomatically to reduce the irritability of the nervous centres. In such cases, antispasmodics and anodynes, bromides, chloral, opiates, and anæsthetics have their use and function. In reflex eclampsia, and even in the toxic forms of the disease

where we can treat the etiological factor, these remedies are useful; but even here the presence of fever necessitates the antipyretics first and the antispasmodics afterward.

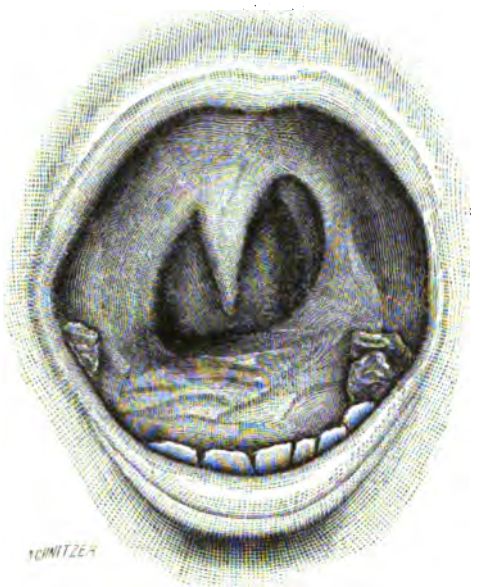
245 Seventh Street.

A CASE OF PRIMARY TUBERCULOSIS OF THE TONGUE—PRESENTATION OF THE PATIENT THREE YEARS AFTER TOTAL EXTIRPATION BY KOCHER'S METHOD.[1]

By WILLIAM T. BULL, M.D.,

NEW YORK.

The history of this patient has already been published by Dr. D. Bryson Delavan, in a paper on seven cases of buccal tuberculosis (*New York Medical Journal*, May 14, 1887); but as two years have gone by since his paper was read, and the man continues to enjoy good health, it has seemed to me of interest to call attention to him once more. It was three years ago, on December 7, 1885, that Kocher's operation was performed at the New York Hospital, for what was supposed to be cancer of the tongue. The man was thirty years of age, and had suffered for six months with an ulcer quite at the base of the tongue, which gave rise to profuse salivation, great pain in swallowing, and had been accompanied with serious depreciation of his general health. The lungs and larynx were sound. A hard gland, the size of a horse-chestnut, existed beneath the ramus of the jaw. The ulcer had an i durated edge and sloughing base. Its situation was so far back that it could only be seen with a mirror; and this fact deterred me at the time from removing a portion of its edge for microscopic examination. At the operation the gland above referred to, together with the submaxillary and lingual glands, were removed, and the muscles of the tongue cut through on a level with the hyoid bone. The wound healed, without complications, in six weeks, and his general health improved rapidly. He gained thirty-five pounds in weight before leaving the hospital. Since then he has continued in robust health. The microscopic examination by Dr. George L. Peabody, pathologist to the New York Hospital at the time of operation, left no doubt as to the tuberculous nature of the disease.



At the present moment this case presents several interesting and instructive features.

1. By a *radical* operation the man has been saved from a disease quite as destructive in its career as cancer.

2. Notwithstanding the loss of the entire organ he is able to speak sufficiently clearly to enable him to pursue his daily avocations without attracting attention. He was taken by an ambulance to the New York Hospital, two weeks ago, for a fractured leg, and it was only within a day or two that his defects in speech were noticed.

3. He is *positive* that the sense of taste is as acute as it ever was.

4. The satisfactory performance of the functions of speech and taste, after so serious mutilation, should encourage us to have confidence in the results of this operation when practised for carcinoma. It is in theory the best of all radical operations for that disease, if we except amputation of a limb; for by it we are able to remove not only the parts affected, but all the tissues and glands next in order of invasion.

The following is a more detailed description of the present condition. On a front view no deformity is perceptible. On looking at the right side, the cicatrix is drawn out of sight under the jaw, and is not unsightly, though there is a decided depression of the submaxillary fossa. The movements of the jaw are perfect. The floor of the mouth is covered with mucous membrane, the muscular layer beneath presenting some small irregularities (see illustration). The isthmus of the fauces is slightly narrowed, because by the cicatricial contraction the right anterior pillar of the fauces has been drawn down and to the left. (In the first six months after operation I twice divided this band with scissors.) His sense of taste I have not tested in any way. In speaking he has no difficulty with vowel sounds, and the chief defects are with the consonants. He pronounces *g* like *v*, *k* like *p*, *t* like *p* or *d*, *q* like *pooh*, *m* like *n*, *k* like *p*, *ch* (hard) like *h* (as in "horus" for chorus), *ch* (soft) like *f*, *x* like *s*, and *th* like *f*. These are the most marked peculiarities; but the words are easily understood by the context, and he finds no serious difficulty in making himself understood. A word may be said as to the error in diagnosis. A number of such errors have been recorded. Batlin ("Diseases of the Tongue," p 291) says: "All the primary tuberculous ulcers of the tongue described and examined by Nedopil had been cut out under the impression that they were cancerous. To this I may add that the manner of dealing with them thus summarily was the best that could be devised both for tubercle and cancer, and if the same decisive method were adopted in the case of all doubtful ulcers of the tongue, there would be a striking diminution in the number of deaths from lingual carcinoma." The microscopic examination of a section of a portion of the edge of the ulcer, together with search for bacilli in scrapings from the surface, will generally enable one to make a diagnosis, and I have been of late in the habit of making such an examination in every case before beginning treatment.

35 West Thirty-fifth Street.

[1] A paper read before the Surgical Section of the New York Academy of Medicine, December 10, 1888.

The Privilege of being a Doctor.—Mr. Crespi says, in the *Provincial Medical Journal*, November, 1888, that "the greatest privilege which the doctor enjoys is the facilities he has of getting to know the inner life of all classes. Man is always worth studying, and no human being is without certain traits which proclaim his Divine origin. The rudest artisan, as well as the humblest peasant, presents features which repay careful scrutiny, while the most illustrious rulers of mankind often exhibit littleness and bad traits that excite pity. The doctor knows his clients at their best and their worst, that is, he sees them when they show themselves as they really are, and off their guard; he therefore, perhaps, more than anyone else, can estimate the greatness and the devotion which often hide in the lowly cottage, while he sees the vices and evil passions of the great. Doctors ought to be profound masters of human nature, and should enrich the world with powerful delineations of character and with philosophical treatises which should rank among the brightest gems in literature."

THE IMMEDIATE APPLICATION OF FORCEPS TO THE AFTER-COMING HEAD IN CASES OF VERSION WITH PARTIAL DILATATION OF THE CERVIX.[1]

By H. C. COE, M.D., M.R.C.S.,
NEW YORK.

It is not my purpose to enter into a discussion of either the advisability of extracting the child immediately after version, or the best method of manual extraction to be practised in ordinary cases. I limit myself entirely to cases in which the os is just sufficiently dilated to admit the introduction of the hand and the performance of version, the soft parts being more or less rigid, and in which the life of the child is imperilled by even a slight delay in the extraction of the head. There is considerable difference of opinion among writers on obstetrics regarding the application of the forceps to the after-coming head under these circumstances, so that it is with much satisfaction that I find my opinion on the subject supported by such an authority as Lusk, who affirms that "where the arrest of the head is due to stricture of the os externum or internum, the forceps will sometimes bring the head rapidly through the cervix when traction upon the feet only serves to drag the uterus to the vulva" ("Science and Art of Midwifery," p. 366). Barnes ("Obstetric Operations," p. 67) teaches essentially the same. Busch and later English writers attribute their low infant mortality after version to the prompt use of the forceps. Whether this is true or not, I regard it as a matter of regret that the application of the forceps to the after-coming head has become a comparatively rare obstetric operation. I never saw it practised in the Vienna clinics, probably because the conditions happened to be such as to render it unnecessary. The following unsuccessful cases will serve to illustrate the point which I wish to make:

Case I.—(Seen with Dr. J. B. Hunter.) Primipara, aged thirty-five. Moderate contraction of pelvis anteroposteriorly, with rigidity of soft parts; albuminuria and œdema of face and ankles; severe headache, eclampsia imminent; so that labor was induced within two weeks of term Cervix dilated with Barnes's bags, version, and immediate extraction, as the fœtal heart was rapid and irregular, and a living child was most earnestly desired. The head (which was large) was encircled by the non-dilated cervix and could not be extracted; the cord had stopped pulsating, when the forceps were applied. The head was delivered in a few seconds, the perineum being torn through the sphincter. I worked over the child for an hour, but could not resuscitate it. The mother made a good recovery, the perineal wound healing with a primary continuous suture.

Case II.—(Seen with Dr. J. L. Morrill.) Multipara, aged thirty-five. She had borne two or three dead children, all of whom were delivered by high forceps, there being a moderate contraction of the conjugate. The pains were ineffectual, and after several hours the head remained movable above the brim, the cervix being partially dilated. Version was performed, but the head was grasped by the cervix; after prolonged efforts had been made at manual extraction the forceps were applied and the head was easily delivered, but the child was dead.

Case III. (Infant Asylum.)—Primipara, aged sixteen years and eight months. Suppression of menses at fifteen, and they did not appear again before pregnancy.

March 21st.—Urine examined on account of œdema of lower extremities, and found to contain fifty per cent. of albumin. Under treatment the œdema disappeared, and the amount of albumin diminished two-thirds.

March 27th, 3 A.M. The patient was suddenly attacked with convulsions, which recurred at frequent intervals and were unusually severe. The resident physician, Dr. Davis (who conducted the case throughout with excellent judgment), at once administered an anæsthetic and introduced water-bags, so that I was able to turn at 6 A.M. The after-coming head was tightly grasped by the cervix, and time was thus lost in attempts at manual extraction. It was easily delivered with forceps, but the child could not be revived. The perineum was torn partially through the sphincter, in fact, it was lacerated at the outset by the introduction of my hand. It was sutured with silver, and the patient had good retentive power at the end of six months. She had two convulsions after delivery, became comatose, had complete suppression of urine, and developed general œdema of the lungs. Under the use of pilocarpine, dry cupping, and diuretics she recovered; the albumin disappeared in a day or two, and on the twelfth day after delivery she sat up.

Case IV. (Infant Asylum.)—Sextipara, aged thirty-eight. Pelvis normal. Confinement expected the latter part of April.

June 1st.—There was a sudden great increase in the amount of liquor amnii; cause unknown. Her health deteriorated rapidly; the heart-action was at times alarming, and on June 13th labor was induced.

June 14th.—The cervix was partially dilated with water-bags, after she had had slight pains for upward of twelve hours. Membranes ruptured; head large and would not engage. Uterus atonic by reason of over-stretching from hydramnios; the water escaped slowly.

June 15th.—Constant pain in abdomen, but uterine contractions feeble, and patient exhausted, with tumultuous heart action. Head freely movable above the brim; fœtal heart rapid and irregular. Version was easily performed at 7 P.M. The head was arrested at the brim, being firmly grasped by the cervix. Several minutes were wasted in futile attempts to extract it. The forceps were then applied, after the pulsation in the cord had stopped, and the head was delivered with some difficulty. The perineum was only slightly torn, but the patient had enormous hemorrhoids, which ruptured and gave rise to sharp hemorrhage, requiring the application of artery-forceps. Weight of child, eight pounds and three ounces. Head large and incompressible, the posterior fontanelle being closed. The child was resuscitated after a long struggle, but died in convulsions seven hours later. Autopsy showed extreme cerebral congestion. The mother recovered slowly, after presenting alarming heart-symptoms, and a general subnormal temperature, except on the fifth day when it rose to 102° F. without appreciable cause, but fell at once. She had in all probability a fatty and dilated heart. [I am indebted to Dr. Davis for notes of the last two cases, which occurred in my service at the Infant Asylum.]

In citing these examples of unsuccessful extraction I need only add, in order that the difficulties may be assumed as real, and not apparent, that the operator possessed a fair amount of experience in this class of cases, and that he was in each instance assisted by skilled physicians and nurses, so that all the elements of success were present. The obstacle to delivery was the same in every case, *i.e.*, the head was grasped by the rigid, partially dilated cervix in such a manner that traction upon the trunk simply dragged the uterus down to the vulva without liberating the head at all; moreover, it was impossible to introduce a finger into the child's mouth. Pressure upon the fundus uteri simply forced the organ downward, but did not advance the imprisoned head. Of course the large size and premature closure of the fœtal head in one of the cases reported, and the narrowing of the anterior conjugate in another would partly account for the arrest at the brim, but these factors do not concern me now. I wish to invite discussion on the single topic which I proposed. I believe that in each of the four cases cited the child would have been saved if the forceps had been applied just as soon as I had discovered why the head did not escape. The application of the forceps to the after-coming head is quite easy if the child's trunk is strongly extended, and the entire operation

[1] A paper read before the New York Academy of Medicine (Section in Obstetrics and Gynecology) December 27, 1888.

usually occupies only two or three minutes. Of course there is considerable risk of lacerating the cervix and perineum by delivering so rapidly; but what is that when a living child is obtained which would otherwise have been sacrificed when on the threshold of safety? Those of us who are attached to lying-in hospitals, and are constantly striving to keep our maternal mortality at the lowest possible figure, are apt to attach comparatively slight importance to the survival of the child. In private practice, however, we must view the matter in an entirely different light. It often happens that we are consulted by an old primipara, who has been led to believe that she cannot have a living child, or by a multipara who has borne several dead ones. Such women are extremely anxious that the infant should be saved at all hazards, and will make light of severe lesions if we are successful in obtaining their wish. I feel that some apology is necessary for introducing such an old theme, but since writing the above my attention has been directed to a short, but suggestive, paper by Dr. P. M. Schiedt, of Philadelphia, on "The Treatment of the After-coming Head" (*American Journal of Obstetrics*, March, 1888). The writer holds even stronger views than those which I have outlined, and his arguments and statistics are quite convincing. Among other indications for the use of forceps in this connection he mentions that which I have discussed. I quote from his concluding sentences: "The most vigorous supporters of the manual method declare that it requires from five to six minutes to extract the child's head, while Freudenberg and others say that the forceps should be applied and the head extracted in from two to three minutes. It is manifest that the difference in time, at a moment so critical, will result in the saving of many children. Time is the great factor, and by the forceps time is saved."

A NEW METHOD OF TREATING GONORRHŒA.[1]

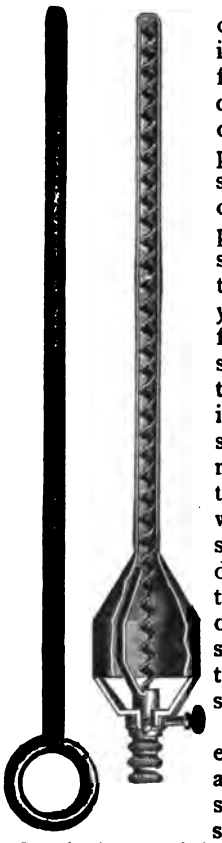
By JOSEPH ZEISLER, M.D.,

PROFESSOR OF GENITO-URINARY AND SKIN DISEASES, POST-GRADUATE MEDICAL SCHOOL; MEMBER AMERICAN DERMATOLOGICAL ASSOCIATION, CHICAGO, ILL.

During the last few years considerable progress has been made on the subject of gonorrhœa. The discovery of the specific cause—the gonococcus of Neisser—has thrown a great deal of light upon the nature of the disease. It has made it possible to separate the same from other similar, yet vastly different processes, and we are enabled to test the multitude of remedies used heretofore by their direct action against those microbes, etc. On the other hand, the development of endoscopical methods has opened a wide field for research, more especially in regard to the chronic forms of gonorrhœa, and our ways and means to treat these conditions have been materially improved. But, unfortunately, the treatment of the acute stage has so far remained just as unsatisfactory as ever, and still amounts to a *laisser-aller;* for no honest observer will deny that the composition of the various injecting fluids makes very little difference, and that hygienic and dietetic measures are of much greater value to our patients. As I intend here to speak of an entirely novel plan of treatment, I shall refrain from discussing any of the older methods; nor can I give any bibliographical introduction to my subject.

The new plan, with which I became familiar through the kindness of Dr. C. S. Pixley, of Elkhart, Ind., consists in introducing dry powders into the male urethra. The idea of this treatment is not entirely original; chronic otitis media and obstinate cases of leucorrhœa have long been managed by the application of powdered boric acid. But great difficulty was experienced in finding a proper instrument through which to convey the powder into the male urethra. After many attempts and laborious trials it has at last been perfected to the shape in which I present it herewith.

The instrument consists of three principal parts, two of which resemble very much the original form of the urethroscope, as devised by Désormeaux, Fenger, and others; namely, first, a cannula, with a cup attached to one end, second, an obturator, to facilitate the introduction; and third, a hollow spiral, whose object is to convey the powder through the cannula into the urethra. The cannula has, in the present form of the instrument, a length of six inches, and a diameter of about one-fourth inch (corresponding to No. 20 of the French gauge). The cup has a capacity for about two drachms of dry powder; a narrow bridge with a set-screw is attached transversely to the cup, in order to fasten the spiral in its proper position. The length of the spiral corresponds exactly to that of the cannula, so as not to protrude beyond the lower end of the same when fully inserted; the upper end of the spiral is formed by a milled head, on the top of which is an arrow, indicating the direction in which the spiral should be turned. Just below the milled head is a groove, into which fits the set-screw. Below this groove, to what may be called the neck of the spiral, is attached an agitator, which during the turning continually moves the powder toward the spiral. The obturator, which needs no further description, transforms the cannula practically into a solid, straight, urethral sound.[1]



Cut, showing a vertical section of the instrument, with the spiral in its place. Half size.

The instrument could, of course, be easily manufactured in different sizes, although the present (No. 20) will answer for most cases. The length of six inches will allow the introduction up to the membranous urethra only, which, in acute cases, where the inflammation has not invaded the deeper parts, will be all-sufficient. With a slight modification, increasing the length of the cannula and spiral, and placing the cup under an angle, the instrument could also be adapted for the purpose of treating the deepest parts of the urethra.

Mode of operation: The patient is directed to evacuate his bladder perfectly; next the urethra is thoroughly washed out with a weak solution of permanganate of potassium (1 : 10,000), or some other suitable alkaline solution; this may be best done by the well-known retrojector. Now the urethra is dried as perfectly as possible by gently stripping the penis with a clean towel. The patient is then placed in a recumbent position, and the instrument, with the obturator inserted, is lubricated (best with glycerine) and gently introduced into the urethra back to the pars membranacea. The obturator is now gently withdrawn, so as to cause the least possible irritation of the mucous membrane, the spiral substituted therefor, and fastened by the set-screw into its place. The medicament is now placed into the cup, and by constant turning of the spiral in the direction indicated by the arrow, conveyed through the cannula to the deep urethra. At first very little resistance to the turning of the spiral is felt; as soon as the powder begins to be deposited in the urinary channel, the operator will experience a decided resistance. The instrument may now be slowly withdrawn, and in this way the whole urethra filled with the powder. The operator can easily

[1] A paper read before the Chicago Medical Society, December 17, 1888.

[1] The instrument is furnished by Haussmann, McComb & Dunn, in Chicago.

regulate the amount of powder he wishes to introduce. It is not possible to pack the urethra too firmly, as the instrument is in a certain measure self-regulating. The operation completed, a small quantity of the powder is placed around the meatus and the glans penis, to keep these parts as dry as possible from the ensuing discharges, and the patient directed to keep the same always covered with dry absorbent cotton.

If properly executed, the whole operation will cause very little inconvenience to the patient; by the previous use of a cocaine solution it can be made absolutely painless. The patient will, during the next few hours, naturally have a sensation of fulness; by and by, as the powder is dissolved and eliminated by a profuse watery discharge, the urethra will be emptied within four to six hours.

The number and frequency of operations will depend on the gravity of the symptoms; one application daily will usually be sufficient during the first few days (Dr. Pixley has often done it twice daily when practicable); later it may be done only every second day, or even at longer intervals.

In the composition of the powder, boric acid has been adopted as the basis, to which may be added different drugs, to meet the requirements of the case. A long series of experiments will probably be necessary to finally determine what combinations may be of most value. For the present, the following suggestions may be useful: In the beginning the mildest possible powders should be used, such as pure boric acid, or, as Dr. W. E. Morgan recommends, calomel, one part; bismuth subcarbon., two parts; boric acid, twelve parts. With the decrease of inflammatory symptoms the powder can be made more astringent by an addition, in proper proportions, of alum, subnitrate of bismuth, hydrastine, etc. Reports of the poisonous effects of boric acid after packing the vagina have lately been published;[1] but with the comparatively small quantity of the acid used in the urethra no such result seems here possible, except in rare cases of idiosyncrasy.

The treatment as described has been practised by Dr. Pixley for the past two years, and by Dr. Morgan, of this city, myself, and a few others for several months. The number of observations is as yet not sufficiently large to give any valuable statistical data; but our experience so far has been favorable enough to justify the placing before the profession at large of the new method, and to strongly recommend it for a fair trial.

Looking upon this plan of treatment merely from a theoretical stand-point, we shall find in it some points which must commend it to our favorable consideration. Above all, it is based upon antiseptic principles. The inflamed and suppurating mucous membrane remains in contact with a mild yet powerful antiseptic or astringent agent for several hours in succession; this will surely appear more effective than the occasional use of an injection during a few minutes. The diseased urethra is in this way placed under nearly the same conditions as any suppurating cutaneous surface. The purulent discharge will immediately be made innocuous, and its infecting influence upon uninvaded parts will be checked.

From the actual observations made, the following experience has been gathered. It is desirable to begin the treatment as early as possible. The acute inflammation forms no contra-indication against the use of the instrument. The effect of the first few powder applications is to deprive the secretion of its purulent character and to change it to a mucous fluid; a few more treatments will result in rendering the discharge only serous in character, when a mild astringent injection will terminate the course of the disease in a few days. The duration of the disease has in this way in all cases been materially shortened. Chordee, usually so troublesome, has in every case been greatly relieved. Epididymitis, cystitis, stricture, or any other complication, was not known to follow any of the cases treated in the foregoing manner. While the benefit derived from the treatment was not always equally great, there was never the least harm done by it.

I must frankly admit that I was at first, before having tried it, very far from being enthusiastic about the method, as I had some theoretical objections to it; my practical experience, however, has led me to look upon it with a great deal of confidence, and the hope that we may really have made a step toward improving the rather deplorable condition of the treatment of gonorrhœa. Still, I wish the foregoing to be regarded merely as a preliminary communication, being prompted by the desire to invite others to try the new plan. With the co-operation of a larger number of observers it will soon be possible to arrive at definite conclusions regarding the value of this novel method.

CREOLIN IN THE LOCAL PREVENTIVE AND CURATIVE TREATMENT OF INFECTIOUS THROAT DISEASES.

BY F. W. KOEHLER, M.D.,

LOUISVILLE, KY.

IN Nos. 17, 18, and 19 of the current volume of the *Wiener Medizin. Wochenschrift*, Dr. James Eisenberg describes a series of experiments made with the new antiseptic creolin. He shows it to be an extremely powerful germicide, and yet, even in large doses, altogether harmless to man. These qualities made it appear to me an ideal remedy for the preventive and curative treatment of infectious throat troubles. Adults can use gargles of the ordinary poisonous antiseptics, like the bichloride of mercury, but for children something is needed which can be safely swallowed. Soon after I had read Dr. Eisenberg's article I procured a supply of the creolin, and have since used it to the exclusion of other local applications. My success with it has been very pleasing indeed. In treating infectious throat troubles I now always put not only the patient, but also all the well members of the household on the creolin treatment. Thus I have prevented, I think, diphtheroid sore-throat from going through entire families of children, which it had previously, under other modes of treatment, always done. But it is as a preventive of true diphtheria that I expect most from the creolin. Dr. Eisenberg's experiments show that no form of pathogenic germ can resist its action; and it is therefore reasonable to suppose that the germ of this disease will also succumb to it. Recently I was called to see an old lady, who, a day or two after exposure to a case of diphtheria (proved to be so by paralysis occurring several weeks afterward), was taken sick with rigors, fever, and sore-throat. Almost simultaneously her daughter and son-in-law were taken in the same way; but her little grandchild, a boy of four years, showed no signs of the disease when I was called. I at once, however, put him, as well as the others, on the creolin treatment. The child, although always rather predisposed to throat and bronchial trouble, escaped an attack altogether, and his parents and grandmother recovered promptly.

Diphtheria is certainly one of the most dreadful diseases that confront us, and any treatment that might reasonably be expected to prevent its spread should be given a trial. I am inclined to believe that if the mouths, throats, and nasal passages of children were kept as clean as their faces, there would be much less of the disease. When diphtheria prevails, no child's toilet should be considered complete until the upper air-passages have been thoroughly douched with some suitable antiseptic; and in the long list of such agents I know of none that fulfils the requirements so well as creolin.

It is a well-known fact that the secretions of the nose, mouth, and throat swarm with many kinds of micrococci. Under ordinary circumstances they are harmless, but there is reason to believe that under favorable conditions

they may become pathogenic. What these conditions may be, we do not as yet know. Possibly, however, a slight change in the character of the secretions, brought about by a simple inflammation from exposure to cold and wet, may be sufficient to make a harmless bacillus virulent. A change in the culture-medium is known to change the character of micrococci. Bacteriologists agree that the virulent bacillus anthracis can, by cultivation outside the human body, be made harmless. Contrarywise, Pasteur has shown that the virus of swine-plague can be made more virulent by transmitting it through a series of pigeons. These facts have an important bearing on the vexed question of identity or non-identity of diphtheria and diphtheroid sore-throat. Cases constantly occur seeming to prove that from exposure to a plain and simple case of follicular tonsillitis there may arise one of virulent diphtheria, and *vice versa*. When such facts as quoted above are established, what is there remarkable in the benign germ of diphtheroid sore-throat becoming, by successive suitable cultivations, the virulent cause of diphtheria? Admitting the probability of the thing, does not the necessity of rendering the parts usually affected by the disease as nearly aseptic as possible become doubly important? But even without admitting it, does it not seem that we should, when diphtheria prevails, use all possible diligence to destroy the poison of the disease before it has had time to take root? I hold it a matter of conscience to induce those in charge of children to keep them medically as well as æsthetically clean. In creolin we have an agent cheap, effective, and harmless. Possibly the peroxide of hydrogen may also be suited to the purpose; but Dr. Gifford tells us in THE MEDICAL RECORD for September 1, 1888, that even the weakest solutions recommended "cause smarting of the mucous membranes," and that the fifteen volume solution is "sharply irritating." The one and two per cent. solutions of creolin that I employ have not this objection, and that they are potent germicides Dr. Eisenberg's experiments prove.

THE MODE OF ACTION AND VALUE OF ANTIPYRINE IN TYPHOID FEVER.[1]

BY N. S. DAVIS, JR., A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, CHICAGO MEDICAL COLLEGE; PHYSICIAN TO MERCY HOSPITAL, ETC.

THE topic that I wish to consider in connection with this discussion of typhoid fever opens the whole subject of the value of chemical antipyretics in this disease. In the brief time allotted to me, however, I can only outline the arguments upon one side of the question.

Antipyrine has been used in typhoid fever only as an antipyretic, and in valuing the drug we naturally are led to inquire, first, How does it depress temperature? The production of heat is accomplished by an increase of cellular metabolism, which undoubtedly is greatest in the muscles and the large glandular organs. It is under the control of, and excited by, a thermic centre or centres in the nervous system. In typhoid fever there occurs a general systemic poisoning. It seems probable that increased bodily temperature is only one manifestation of this poisoning, and is due to a toxic influence exerted upon the central nervous system. Bodily temperature in this fever may, therefore, be depressed either, 1, by destroying the poison; or, 2, by counteracting its effect upon the heat-controlling portion of the nervous system; or, 3, by aiding in the elimination of heat from the body.

Antipyrine, it has been supposed, in part lowers temperature by increasing elimination, as it causes dilatation of the peripheral vessels,[2] and in fever usually provokes copious perspiration. But Rosenthal has shown that radiation of heat is not increased by it.[1] The experiments of H. C. Wood, both upon feverish and non-feverish animals, have shown, too, that heat-dissipation is lessened by it, but proportionately not so much as heat-production is.[2]

The results of experimentation upon animals, and of clinical observation upon man, are almost unanimous in showing that tissue-change is lessened, and that thus heat-production is very greatly diminished. It is undoubtedly to this action, almost exclusively, that antipyrine owes its antipyretic power. It lessens the amount of urea excreted, and Lepine and Porteret have shown that it diminishes the transformation of hepatic glycogen into sugar.[4] These changes are probably accomplished by a direct action of the drug upon the gland-cells of the kidneys and liver. Undoubtedly, tissue-change is diminished in the muscular structures, as well as in the important glandular ones.[4] It is not established, however, that this apparently universal inhibition of metabolism is due to the action of the drug upon all the tissues; on the contrary, it has been shown that it is due to an action upon a portion of the nervous system in or above the medulla, by which metabolism in the tissues is controlled.[5]

Antipyrine does not destroy or eliminate the pyrogenic poison, but counterbalances the action of the latter upon the nervous system, very much as atropia does the action of pilocarpine upon the sweat-glands. We are led to this conclusion because the drug often lowers even normal temperature, and will depress a fever temperature, no matter what may be its cause—whether it is the result of an artificial over-heating of the entire body, or of the action of a septic poison, or of inflammation. We are led to the same conclusion by the fact, which clinical experience has demonstrated, that although by chemical antipyretics, such as antipyrine, we may keep the temperature almost continually depressed, the body does not stop wasting, and the typhoid fever is not aborted, nor, as a rule, is its course materially modified.

Does the simple depression of temperature accomplish good? This question involves another: Does pyrexia in itself endanger life? Neither of these questions can be answered with certainty. The recent discussion[6] by Liebermeister and Unverricht in regard to them have been most instructive. In my own experience I have found that those cases that have been treated by antipyrine ran no shorter course and recovered no more quickly on the average than those treated without chemical antipyretics. And I find the largest portion of the most recent evidence fully confirms these observations.

The probable explanation of this lies in the fact that the poisons which provoke the fever diminish tissue-repair much more than they increase tissue-disintegration. Indeed, the total amount of tissue-disintegration during the fever is less than during health, but compared to tissue-repair, under the same circumstances, it is greater. Moreover, while in typhoid fever tissue-disintegration is relatively great, it is incomplete, so that the chemical bodies which in health we look upon as the final result of tissue-disintegration, such as urea, are diminished in amount; but extractives and products of incomplete disintegration are increased in proportion to the severity of the fever. Among these incomplete products are probably leucomaïnes, and possibly pathological leucomaïnes. Although antipyrine diminishes the complete disintegrative changes of the tissues, and thus lowers temperature, it does not aid in the upbuilding of the tissues or in a restoration of

[1] A paper read before the Chicago Medical Society, December, 1888.

[2] Numerous observers have noticed this effect. A complete review of this action of antipyrine is given by E. Marylino, in the Zeitschrift für Klinische Medicin, Bd. 14, Heft 4; also see Beyer, The American Journal of the Medical Sciences, 1886.

[1] Centralblatt für Physiologie, No. 5, 1888.

[2] H. C. Wood: Therapeutics; Its Principles and Practice, p. 628, 1888.

[3] Le Semaine Médicale, April, 1888.

[4] Lepine and Porteret have shown that relatively to health in antipyrinized animals muscular glycogen is increased twenty to twenty-eight per cent. Le Semaine Médicale, August, 1888.

[5] The dependence of antipyrine upon the nervous system, in order to produce antipyresis, has been shown in various ways. In the last few months Sawadowski has shown that antipyrine cannot depress, nor putrid matter elevate, the temperature, if the cord is cut above the atlas Centralblatt für Physiologie, No. 5, 1888.

[6] Deutsche Medicinische Wochenschrift, 1888.

equilibrium between repair and disintegration, therefore loss of flesh and strength persist in spite of a prolonged artificially depressed temperature.

Pyrexia in itself, when within the usual bounds of typhoid fever, does not endanger life, for the deaths from the disease do not correspond absolutely to the height of the fever. On looking over the record of forty-five cases that I have observed in hospital and private practice during the last eighteen months, I find that the fatal cases were not those with the highest temperature. The danger in typhoid fever is from the extent of the intestinal ulceration, from perforation, from hemorrhage, or from complications such as pneumonia or disturbances of the brain, and not from pyrexia. Unverricht has recently collected an abundance of evidence to show that danger does not arise from increased bodily temperature.[1]

The effects of chemical antipyretics upon the course and life-history of fever emphasize the fact that pyrexia is only a symptom of the pathological state with which it is associated, and does not in itself constitute fever. I think, then, we are justified in concluding that antipyrine, by depressing bodily temperature, does not favorably modify typhoid fever.

If, then, antipyrine is not useful in typhoid fever as an antipyretic, can we employ it advantageously for any of its other ways of action?

From the skin it uniformly provokes profuse perspiration. This does not add to the comfort of the patient, although it may aid in dissipating bodily heat. As in other conditions of the human system, antipyrine will, in typhoid fever, often cause a rash, whose presence increases the sufferer's discomfort.

Upon the stomach and digestion it exerts no noticeable influence. It is rarely nauseous or otherwise especially unpalatable. It has been found to be an excellent hæmostatic. But no favorable results have been reported from its use in typhoid fever accompanied by intestinal hemorrhage. Antipyrine was employed steadily in a case of typhoid, with frequent, and finally fatal hemorrhages, that was under my observation a year ago in Mercy Hospital, but no beneficial influence was observed upon the bleeding. This is undoubtedly due to its ready absorption from the upper part of the alimentary canal, and its failure to reach the bleeding surface except in a very dilute form through the blood. Nor does antipyrine appear to exert any favorable influence upon the intestinal inflammation.

Antipyrine in therapeutic doses has little or no power of destroying the red blood-cells, as antifebrine, thalin, and many other antipyretics have. If given in very large doses, the skin, and especially the lips, may become livid in color or cyanotic from the formation of met-hæmoglobin. I have seen this effect produced in two cases of typhoid fever from the administration of only fifteen grains. In each of these cases other toxic symptoms were present. The evidence in regard to its action upon blood-pressure is somewhat contradictory. It seems probable, however, that moderate doses increase blood-pressure, and that larger ones reduce it. In typhoid fever I have been unable to satisfactorily demonstrate any effect upon arterial tension from its use. The sense of touch upon examining the radial artery recognized no change. With the sphygmograph I have made too few observations to be able to deduce from them positive evidence. Of three cases from which sphygmograms were obtained, both before and at varying intervals after the administration of the drug, no apparent change was noticed in two, but a slight lowering of blood-pressure, or increased dicrotism, was observed in the third.

It is admitted that the urine is almost uniformly lessened in amount by antipyrine, no matter in what condition of health it is administered. More marked is the diminution of the amount of urea excreted.[2] These effects of the drug in typhoid fever have been confirmed by many observers. They appear to be due to an action upon the kidneys, suppressing the free excretion of urine and urea. For this reason waste matter is apt to accumulate in the blood. I cannot learn that studies have been made in typhoid cases, treated by antipyrine, upon the production or diminution of the extractives and products of complete metabolism, or of their excretion from the system. I believe the toxic effects which have been observed with comparative frequency in this disease from therapeutic doses of antipyrine, are to be in part explained by this action of the drug upon the kidneys. Since many typhoid cases will tolerate very large quantities, it seems probable that this poisoning is due to changes in the action of the tissues, which are not constant, that exist prior to the administration of the drug. Toxic symptoms I have myself seen developed several times in two typhoid patients from ten and fifteen grain doses. The symptoms were a feeling of universal coldness, of great weakness, and of imminent dissolution. The patients appeared ashen in color, the skin was covered with a cold, clammy perspiration, the pulse was quick, small, and soft, the respiration not materially changed in frequency, but was maintained with slightly increased effort. These symptoms showed themselves in half to three-quarters of an hour after the administration of the drug, and reached their climax in another half-hour, and only gradually disappeared. Very considerable lowering of temperature took place; in one case it fell from 102.5° to 97.8°, and in the other from 103.5° to 99.6°. Unfortunately no urinalyses were made either immediately before or after these attacks. The fatal cases of poisoning by therapeutic doses are said to have occurred with symptoms of collapse. But these are not the symptoms which physiologists obtain from the drug when it is administered in toxic doses to lower animals. Then convulsions, opisthotonus, and increased reflex[1] activity are produced. Last year, in another communication upon antipyrin,[2] I suggested the probability that poisoning from therapeutic doses occurred in those persons in whom the kidneys acted imperfectly or were diseased prior to the administration of the drug, and was due to the retention of toxic matter, the product of imperfect or pathological metabolism. The comparative frequency with which such poisoning occurs in typhoid fever is impressive. In the literature at my hand I find records of the development of toxic symptoms in fourteen cases, in four of which there was fatal poisoning. Of these fourteen, ten were typhoids, and of the four fatal ones, three were typhoids. It is evident, therefore, that the danger of such poisoning is greater in typhoid fever than in other diseases. I have used antipyrine in very many more cases of rheumatism, of neuralgia, and of phthisis, than of typhoid, but have never seen ill effects in any other disease. I believe that in typhoid fever, if the urine is unusually scant, and especially if its nitrogenous elements are much diminished in amount, antipyrine should be used with great caution, if at all.

Aside from the chance of the development of toxic effects from antipyrine, its uniform tendency to diminish urinary excretion lessens greatly its utility in the disease. The necessity for the maintenance of a free secretion of urine has been well put by Robin, who insists that patients who from the beginning of typhoid urinate freely recover better and more quickly than others who do not.[3]

Upon respiration antipyrine exerts no especial influence, and in a considerable literature of the subject I find it nowhere claimed that its use diminishes the bronchitis of typhoid or lessens the frequency of pneumonic complications.

Typhoid fever, as was said in the beginning of this paper, is a poisoning of the entire system. Nowhere do we see its toxic effects better than in the symptoms that

originate in the nervous system. These point to a progressive stupefication of the central nervous system, and, as in anæsthesia and narcosis, when the full effect of a drug is not obtained, delirium often occurs. Usually the delirium is a stupid one, and is characterized by dream-like mutterings during apparent sleep. But we find more rarely, just as from narcosis by drugs, wild delirium, restlessness, and constant wakefulness produced. Antipyrine has seemed to me to lessen these often-distressing nervous symptoms, except in cases characterized by great general exhaustion, when no good seemed to be effected by it. It has never, however, appeared to be as certain and uniform in its action upon the nervous symptoms as some other remedial agents. The well-known and important analgesic properties of antipyrine are not available in typhoid fever.

Finally, I would draw as a conclusion from my own study of the action of antipyrine in typhoid fever, that it is certainly not a specific for the disease, and that it is of little or no use because of the antipyresis which it produces, and of very limited use because of any of its other modes of action. It certainly cannot replace hydropathic treatment, with which it is so often contrasted. It must be remembered, however, that the chief benefit of the latter is not in its antipyretic effect, but in its stimulating influence upon the nervous system, upon nutrition, upon the circulation, and often upon the excretion of urine.

Clinical Department.

REMOVAL OF CYST OF THE MESENTERY—RECOVERY.

By A. N. TALLEY, M.D.,

Columbia, S. C.

On August 26th, last, I was consulted by Miss W——, aged twenty-eight, from a distant part of the State, in regard to an abdominal tumor. She bore a letter to me from her medical attendant, an intelligent physician, in which, after expressing his opinion of the character of the growth, he committed the case to me for ovariotomy. In these views the lady's father, also a practitioner of medicine, fully concurred. The following abridged history of the patient, who, though of delicate frame, presented an appearance of comparative health, was obtained from herself:

About two years ago, and subsequent to an attack of intermittent fever of brief duration, during which she experienced violent pains in the region of the spleen, a slight, movable, and insensitive tumor was discovered in the abdomen, on the left side, on a line with the umbilicus. One year later, in consequence of the gradual enlargement of the growth, medical counsel was sought and ovarian cystoma diagnosticated. As the patient's health was good, and her functions unembarrassed, with the exception of slight menstrual irregularity, no treatment was advised. With the further development of the tumor, however, came the usual disturbances incident to mechanical pressure, which, at the date of her visit to me, had assumed a gravity that demanded relief. When first seen by me the abdomen presented, in size and conformation, the appearance of a woman near the full term of pregnancy. Dulness obtained everywhere, save in either flank, where the percussion note was slightly resonant. Fluctuation was so marked as to leave no doubt of the cystic character of the tumor, which not only filled the abdomen, but occupied the superior portion of the pelvic cavity, pressing the uterus above and to the right of its normal position, though distinctly separable from the latter organ. The urine afforded no evidence of renal degeneration or other serious kidney disorder.

Laparotomy having been determined upon, on August 29th the patient was chloroformed, the abdominal cavity opened, the cyst punctured with a Wells trocar, and three gallons of dark, translucent fluid evacuated, which, on subsequent examination, proved to be slightly albuminous, without trace of echinococci. The adhesions were numerous and strong, and the effort to free the cyst from its visceral attachments by prolonged and careful dissection being only partially successful, it became necessary to sever and ligate portions of the cyst-wall. The pedicle, which was broad and thick, was traced to its origin in the left lumbar region, in close proximity with the second lumbar vertebra, and, as well as could be ascertained, sprang from the mesentery. Its great depth in the abdominal cavity, and its unusual thickness, which necessitated its ligation in sections, suggested the propriety of bringing the ligatures out through the upper part of the incision. The hemorrhage was free, but yielded to hot water irrigation. Keith's drainage-tube was inserted, and the toilet made with strict observance of antiseptic precautions. The uterus and ovaries were healthy.

The shock was profound and protracted, the temperature being subnormal, and the pulse scarcely perceptible for twenty-four hours. Reaction was brought about by the subcutaneous use of nitro-glycerine, with external warmth and active stimulation. On the fourth day the temperature rose to 104° F., and the dressings were soiled with a dark and offensive discharge which made its escape beside the ligature. A flexible tube was inserted, and the cavity washed out with carbolized hot water, causing a speedy reduction of temperature to 99° F. This antipyretic effect of the carbolized irrigations was repeatedly and notably manifested during the progress of the after-treatment.

The subsequent history of the case demands no special or detailed record. Prolonged nausea was relieved by a saline purgative (Rochelle salts), thirst was allayed by warm beef-tea enemata, and flatulence was controlled by the rectal tube assisted by occasional terebinthinate rectal injections.

In six days the wound had healed, save the point from which the ligatures emerged. In twenty-one days the ligatures were thrown off, and in six weeks from the date of operation the lady, with restored health, was enjoying all the comforts of her distant home.

ENDOCARDITIS FOLLOWING CHOREA.

Dr. W. F. Lippitt, Jr., of Charlestown, W. Va., reports the following case: "Annie W——, colored, aged sixteen years. History of inflammatory rheumatism and subsequent 'heart troubles' on both sides of the family. Has herself never had rheumatism. In April, 1888, came to me complaining of pains in the head and stomach, and absence of the menstrual flow. I treated her with tonics and potassium permanganate, as advised then, without result, and without bad effect on the digestive system. She soon developed violent general chorea, which was successfully treated by tonics and galvanism. Recovery from that was followed by sharp pains in the chest and side, succeeded by general anasarca and ascites so great as to seriously interfere with breathing, and only relieved by a combination of calomel, squills, and digitalis. No record of heart lesions at that time was kept. Since then she has occasionally been troubled with shortness of breath, pains around the heart, and dropsy, which, though generally relieved without trouble, has been so great as to necessitate active treatment four times in the last two years. She is now much better than at any time within the last two years, has been free from swelling for a longer time, and is improving without treatment. Present condition is as follows: Apex-beat forcible and diffuse; pulse (after walking), 112 to the minute; area of heart dulness increased; epigastric pulsation auscultation reveals a loud murmur at the apex, with the

first sound continued into the axilla, and perceptible at the back; also at the same time a murmur heard loudest at the base of the heart, and conducted into the vessels of the neck. Urine normal. Has never menstruated. This girl, when fourteen years of age, was brought to me on account of amenorrhœa. The age at which menstruation is said to begin, in temperate climates like ours, is from the fourteenth to the sixteenth year. I have found that in all classes it is the exception for it to be delayed longer than the thirteenth year."

VAGINISMUS COMPLICATING THE THIRD STAGE OF LABOR.

Dr. W. F. Lippitt, Jr., of Charlestown, W. Va., writes: "May 8, 1888, when several miles from town, without my instruments, I was called in to see Belle D——, colored, aged twenty, married, pregnant for the first time. I found that, without any assignable cause, labor had come on prematurely. On examination I found the feet protruding from the os. In the intervals between the pains, I could distinctly feel the movements of the fœtus. I gave ergot to insure contraction of the uterus. The fœtus was expelled without trouble. After waiting for some minutes I examined and found the uterus firmly contracted, and the placenta entirely separate and lying loose in the vagina. In making the examination I found the sphincter vaginæ so firmly contracted as to render it very difficult to get my finger into the vagina. Then, knowing that I was safe in doing so, I pulled with a considerable degree of force on the cord, but, owing to the extreme degree of vaginismus, with no result except the separation of the cord from the placenta. I then gave up in despair, and sent to town for my instruments. But after the messenger had gone I thought of the following plan: I placed the patient in the Sims position, put my left thumb into the vagina, my fingers on the buttocks, and by strong traction succeeded in dilating the vagina sufficiently to introduce my right hand and withdraw the placenta. The woman recovered without trouble. The fœtus was ten inches long, female, bones well ossified, finger and toe nails formed and distinct, eyes open, eyeballs well formed, fœtus perfectly formed with the exception of the head, which was of the variety described by Charpentier as Pseudencephalic."

Dangers of Ear Disease.—Before the Liverpool Medical Institution (*The British Medical Journal*), Mr. Richard Williams read a paper on three cases illustrating the dangers of ear disease. He pointed out that patients and medical men too often neglected chronic discharge from the ear, trusting to it ceasing in time. As a matter of fact, fifty per cent. of the cases of cerebral abscess were due to old-standing ear disease. Mr. Williams's first case was one of otorrhœa and polypus, with disease of the mastoid cells, producing septicæmic symptoms. The second was a case of abscess of the temporo-sphenoidal lobe, following chronic otorrhœa. In the third, thrombosis of the lateral sinus took place, with probably basilar meningitis. In all three the mastoid process was trephined. The first and third recovered, the second died, owing to the bursting of the abscess into the lateral ventricle just before it was intended to trephine over its seat. The diagnosis between abscess and other cerebral affections was difficult. Optic neuritis was not a reliable symptom for this purpose, as it was absent in the above case of abscess and present in the case of thrombosis. The diagnosis of cerebral abscess was obscure. When once made surgical interference presented no difficulty. In cases such as the foregoing, early trephining of the mastoid cells was to be insisted on, so that the whole cavity might be syringed out, and the infection cut off at its source.

Gum chewing and the Eyes.—A Philadelphia physician asserts that chewing gum injures the eyes, causing dimness of vision, and even optic atrophy.

Progress of Medical Science.

Antisepsis in New-born Children.—For the avoidance of septic diseases in new-born children the following rules are recommended by Dr. Miller: 1. With regard to cases of pyæmia, it is not generally in our power to prevent the septic infection of children during fœtal life. Accoucheurs must be particular to enforce rigid antiseptic conditions during the last days of pregnancy and during labor, this applying to attendants, clothing, instruments, the patient, and the accoucheur himself. 2. To avoid pyæmia in the new-born from a gangrenous or putrid condition of the navel, midwives must be carefully instructed as to proper care of the navel wound after the stump has fallen. The cord should be divided with scissors which have been made aseptic, perhaps by passing them through the flame of a spirit-lamp. The ligature must be aseptic, the stump should be washed in a three- or five-per-cent. solution of salicylic acid or boric acid, and then covered with absorbent cotton. One should endeavor to obtain mummification of the stump as soon as possible, and for that purpose only dry dressings are indicated. Should the navel suppurate either before or after the fall of the stump, it should be carefully washed with a weak solution of carbolic acid, dried, and then receive an application of a two-per-cent. solution of nitrate of silver. After this only antiseptic powders should be used. 3. Since gonorrhœal virus appears to be responsible in some cases for inflammation of the navel, the latter may be avoided by using a two-per-cent. solution of nitrate of silver, the same as Credé has recommended for the eyes to prevent gonorrhœal ophthalmia. In any case in which the mother has leucorrhœa this application should be used, without fail, for the eyes and for the navel. 4. Aphthæ are found in the mouths of almost all children in foundling asylums; some of them have it when they enter, and others get it after they have entered, for it is almost impossible to secure a careful cleansing of the mouth in every child in a hospital after each nursing. Not infrequently the wet-nurses who nurse two babies neglect to cleanse their infected nipples sufficiently, and transmit the disease by this means from one baby to the other. The crowding of children in public institutions favors the extension of such diseases. In atrophic children, after the aphthous membranes have fallen there frequently remain ulcers or fissures in the mucous membrane, which act as avenues for the passage of septic material. To avoid infection, it is desirable in hospitals to insist upon the washing of the mouth at least once daily with an antiseptic solution—perhaps of boracic acid—after which the aphthous membrane should be touched with a solution of resorcin, permanganate of potash, boracic or salicylic acid, upon absorbent cotton, no piece of cotton being used for more than one application. The ulcerated portions should be touched with the nitrate of silver solution. 5. Since infection may be transmitted by the folds of the anus, it is essential in cases of erythema ani and rhagades that there also should be antiseptic treatment of these parts. The same remark applies to intertriginous patches and lesions of the skin of the head or any other portion of the body which may have been produced during labor. 6. The use of antiseptic precautions is also necessary in vaccination. In foundling asylums, where vaccination is performed soon after birth, erysipelas and phlegmonous inflammations have become much less common where antisepsis is employed. 7. The greatest care must be used in washing the skin of new-born infants on account of its ready absorbability. A two per-cent. solution of carbolized oil has been known to produce the most violent symptoms of intoxication. Salicylic acid is also too poisonous when used in solutions of ordinary strength. For very young children boracic acid is much the safest agent for disinfecting purposes, and its general use is therefore to be recommended to midwives. —*Archives of Pediatrics*, December, 1888.

THE USE OF ALCOHOL IN MEDICINE.—According to Professor Binz, of Bonn, alcohol in small doses increases the arterial pressure, in large doses the opposite effect is produced. Alcohol increases the activity of the left ventricle of the heart, and diminishes the moments of rest, and increases the respiration. Alcohol in moderate doses is eliminated by the lungs and kidneys. Alcohol burns up into carbonic acid gas, and water taken into the system. This action produces heat, and is of value to temporarily stimulate and strengthen the system. Alcohol does not increase oxidation. Only such substances can be rightly considered as nutritives which promote the heat of the body without producing any injurious accompanying symptoms. It is known that alcohol in large doses increases the decomposition of albumen, and hence, in many cases of severe illness, tends to hasten the fatal result rather than retard it. Alcohol has the power to reduce the temperature of the body in certain conditions. Moderate doses which do not produce the least symptoms of intoxication will cause a fall of temperature of several degrees. The habitual use of alcohol deadens the heat-reducing property until it becomes no longer observable. Narcotic doses of alcohol reduce the temperature several degrees, and this reduction remains for several hours. All the causes of this fall of temperature are not understood. One of them is an enlargement of blood-vessels of the skin, and an increased radiation of heat. Alcohol seems to be a drug of great value in therapeutics, but it must be given with great discrimination. In a healthy man it is always an injurious drug. A habitual beer-drinker is as much an alcoholist as a habitual whiskey-drinker. It is the duty of physicians to support every effort to break up the indiscriminate use of alcohol as a beverage or medicine, and insist that it be used with therapeutical precision. These views were sustained by the members of the congress, and a general agreement was reached that all possible caution should be observed in the use of alcohol as a medicine, and its changing effects on different individuals.—*The Therapeutic Gazette.*

THE ACID PRINCIPLE OF THE GASTRIC JUICE.—Dr. V. Poulet has conducted a series of experiments with a view to obtain a better knowledge of the gastric juice. His conclusions are given, as follows, by the Paris correspondent of the *Therapeutic Gazette:* 1. The gastric juice of adult omnivorous animals, healthy man, for instance, contains in the first part of digestion hippuric acid alone. Near the end of digestion tartaric acid also makes its appearance. As an exception the two acids may be found, in dyspeptic subjects, present together, from the beginning of the digestive process. 2. The stomachs of all young animals, before weaning, contain almost no other acid than tartaric. 3. All adult carnivora, dogs included, have free tartaric acid in their stomachs. Hence dogs should not be chosen for comparative gastric-juice investigations and experiments; but pigs should be preferred, owing to the similarity of their dental and digestive system. 4. The gastric juice of man, sick or well, never was found, in the experiments tried, to contain lactic or sarcolactic acid; the same was true of animals. 5. Hippuric acid extracted from the gastric juice possesses all the chemical properties of the same acid found in the urine of herbivorous animals. But tartaric acid of like origin somewhat differs from the vegetable acid. It will, for instance, effervesce with sulphuric acid, when heated, and present otherwise some of the racemic acid (para-tartaric) characteristics. 6. The behavior of dialyzed gastric juice with colored reagents is not at all that of free muriatic acid, but that of hippuric and tartaric acids or their acid salts. 7. The intestinal secretion helping to complete the digestive process is invariably acid, and is rendered so by a tartaric acid of the variety already noticed.

ANTIPYRINE IN RHEUMATISM.—Dr. Henry Sokotowski, of Cracow, has made a number of experiments with antipyrine in the treatment of articular rheumatism. Of 86 cases observed by him, 68 were accompanied with moderate fever, 18 were without fever. In the former a complete cure was obtained 29 times, or 42.6 per cent.; in the latter, 7 times, or 18.8 per cent. In the whole number of cases a cure resulted 36 times, or 41.8 per cent. The pain diminished after a few grammes of antipyrine had been taken, and very often disappeared after two or three days, less frequently after a longer time, presenting at the same time fluctuations in its intensity, although after every dose some relief was observed. The swelling continued sometimes longer than the pain. The temperature fell to the normal on the third day at the furthest. The duration of treatment was, on the average, 19 days in the cases with fever, and 32 days in the apyretic cases. The cases in which a complete cure was not obtained were divided into the following categories: 1. The pain and swelling ceased temporarily, but if the drug were withdrawn they reappeared, and afterward the remedy had no influence on the illness (six cases). 2. The pain and swelling ceased temporarily, but returned in the same or in other joints, in spite of the continued administration of the antipyrine (eight cases). 3. The pain diminished temporarily, but the swelling did not disappear (five cases). The drug exerted no influence on the course of the disease in twelve cases. Few or no unpleasant effects were observed during the administration of the remedy. Comparing the results of the treatment of articular rheumatism by antipyrine and salicylic acid, the author found that a cure was obtained by antipyrine in 41.8 per cent., and by salicylic acid in 31.8 per cent. Dr. Sokotowski concludes as follows: 1. Antipyrine deserves more the name of a specific remedy in rheumatism than salicylic acid, because it surely removes all signs of rheumatism, acute and chronic. 2. Its analgesic action, positively confirmed in neuralgia, in hysterical pain, and in tabes dorsalis, by Guttmann, Strzeninski, Sée, and others, very seldom fails. 3. The unpleasant effects very often observed during the administration of salicylic acid, and dangerous in heart diseases, are very rare when antipyrine is given, and therefore do not limit the application of this valuable medicine.—*Przeglad Lekarski*, No. 42, 1888.

SCHEUERLEIN'S ALLEGED CANCER BACILLUS HARMLESS.—This so-called pathogenetic microbe has been thoroughly investigated by Dr. Van Ermengen, who states that he finds it to be entirely inert. Having made pure cultures of the microbe, he injected it intra-venously into dogs, cats, rats, guinea-pigs, etc., with absolutely no results. Even the injection of so large a quantity as 31 minims gave no trouble. Dr. Van Ermengen repeats that the so-called cancer bacillus is a micro-organism very common in dust, air, soil, etc., and is identical with the *bacille rose* found in impure cultivations of bacillus tuberculosis.—*The St. Louis Medical and Surgical Journal*, December, 1888.

SURGICAL TENSION.—Mr. Bryant summarizes his lectures on tension as met with in surgical practice, as follows (*The Lancet*): 1. The pain associated with every form of inflammation of the bone or of its periosteal covering is due to tension, and the severity of the pain is a fair measure of its intensity. 2. In acute inflammation of the bone or of its periosteum, tension is the chief cause of necrosis; and in the subacute and chronic forms it is a potent cause of their chronicity, as well as of the destructive changes which, as a rule, follow. 3. The relief of tension, wherever met with, when the result of inflammation, is an important principle of practice which should always be followed. In bone the principle is most imperative, on account of the difficulties under which natural processes act in that direction, by reason of the absence of elasticity or yielding in bone, and by reason of the anatomical arrangements of its vessels which favor blood stasis. 4. To relieve tension in the softer tissues of the body, the local application of leeches, local or general venesection, acupuncture, aspiration, punctures, and incisions may be requisite; whereas, to carry out the same

practice in endostitis or periostitis, subcutaneous or open incisions down to the bone, and the drilling, trephining, or laying open of bone by a saw, may be required, the choice of method having to be determined by the requirements of the individual case. 5. In the early or hyperæmic stage of inflammation of bone, before destructive changes have taken place, experience seems clearly to indicate that the relief of tension—as indicated by a dull, aching pain, etc.—by means of drilling or trephining into bone, may arrest the progress of the disease, and help toward a cure by resolution; whereas, in the exceptional cases in which this good result does not take place, suffering is saved and destructive changes are limited. 6. In articular ostitis of every kind and variety, and in every stage, this mode of treatment cannot be too strongly advocated, as tending toward the prevention of joint disease. 7. In acute or chronic abscess of bone, diaphyseal or epiphyseal, the abscess cavity must be opened as any other of the soft parts, drained, and dressed in the most appropriate way—the principles of treatment being the same in hard or soft tissues, although they are modified by the anatomical conditions of the parts.

Encysted Stone and its Removal by the Supra-pubic Method.—At a late meeting of the Clinical Society of London (*The British Medical Journal*), several cases of encysted calculus removed by supra-pubic lithotomy were reported. Mr. Fenwick read notes of the first case. The patient had been under the care of Dr. Hine, of Leytonstone, and the symptoms had lasted eight years. The calculus could be felt bimanually, and was subsequently discovered to be hour-glass in shape. The smaller piece (one ounce and a half) was found projecting into the bladder at the level of the left urethral orifice, and the larger portion (four ounces and a half, the size and shape of a large hen's egg) lying in a diverticulum outside the back and base of the bladder. These two portions were connected by a very slender neck. The vesical piece was easily snapped off, leaving the neck protruding from the threepenny-piece-sized orifice of the diverticulum. The position of the opening rendered much dilatation of it dangerous. It was impossible, therefore, to extract the encysted portion entire. Attempts to crush it, by means of lithotrite or forceps, failed. A chisel was guided through the orifice of the diverticulum and laid upon the stone; elastic counter-pressure was afforded by Petersen's rectal balloon. The calculus was then cut through by repeated blows with a mallet. After many shiftings of the pieces and sections in every direction, the stone was chiselled into sufficiently small fragments to allow of their being extracted through the orifice. The wound rapidly healed, and the patient left for the country in six weeks without an untoward symptom. The second case was reported by Dr. J. B. Browne. The patient was a gentleman sixty-eight years of age, seen for the first time last June, with the following history. Lithotrity had been performed five times in less than two years; the first operation was in August, 1886, the last in April, 1888. The earlier operations had only given temporary relief from very distressing symptoms, and the last one had not been followed by any improvement. All the urine was passed by catheter hourly, night and day, and there was constantly recurring intense vesical spasm. On sounding the bladder a stone was detected lying apparently on the floor of the neck of the bladder; it was found very easy to pass over this stone, or rather, stony surface, into the vesical cavity which lay beyond without noticing any calculous matter. The cavity of the bladder was entirely free from stone. Nothing could be felt by the rectum, except a moderately enlarged prostate. The history of the case, the feebleness of the patient, and the need for free drainage of the bladder, determined the choice of operation, and on July 3d Mr. Buckston Browne opened the bladder above the pubes. Directly the finger entered the bladder it encountered, immediately underneath the opening, a stony surface lying level with the surrounding tissues. It was evidently a stone firmly embedded in the floor of the bladder, immediately behind the prostate. The calculus was lifted out by a long and narrow scoop; the finger then passed into a pocket, which went downward and forward toward the rectum, and the right fore-finger introduced into the rectum was only separated by a thin septum from the left fore-finger passed into the vesical pocket. The stone was apparently phosphatic throughout, and weighed a little over a fourth of an ounce. The patient promptly recovered.

Modern Methods of Treating Syphilis.—Dr. Schwimmer has published a comprehensive paper on the modern treatment of syphilis, of which the following *résumé* is given in the *New York Medical Journal*, November 17, 1888: The subject is treated under three headings: 1. The preventive or abortive treatment of syphilis. 2. The methodical treatment of syphilis; and 3. The duration of treatment. The author is a firm believer in the specific nature of the infection and the duality of the soft and hard chancre. He is not an advocate of the excision of the chancre, believing that in most cases the induration is the primary expression of constitutional infection. The early treatment of the disease is advocated in order to prevent the worst after-effects of the dyscrasia. If the sclerosis is not well marked at first, a purely local treatment may be employed during the first three or four weeks. If a well-marked initial lesion is present at the time of the first examination, general treatment should be begun at once. For local treatment caustics should not be used; salol has been found efficacious to promote the healing of the ulcer, and mercurial plaster for the induration. Mercury is the most reliable means for combating the disease, and can be used either internally or externally, preferably the latter, either by inunction or injection hypodermically. The various salts and combinations of mercury are fully considered in their action and mode of administration. Corrosive sublimate is preferred for internal administration, particularly in pill form. Calomel is useful in the treatment of children, and the following formula is commended: Calomel, Dover's powder, each 1½–2 grains; sugar of milk, 45 grains. Divide into ten powders. Of these powders, two to three may be given daily to a nursing infant, and six to nine to a child over one year old, and their use continued for four to six weeks. The protiodide of mercury is less energetic than the bichloride, but useful in slight relapses, while we are cautioned against the use of the biniodide. Tannate of mercury is a reliable salt for internal medication, more active than the sublimate, but not so efficient as the inunction method of treatment. It causes but little disturbance of the digestive tract, and can be administered for a long time in the dose of one grain and a half two or three times daily, either in solution or in pill form. The treatment by mercurial fumigation is not regarded with favor, on account of its unhandiness. Mercurial baths are of little service in the treatment of syphilis in adults, but very good in that of congenital syphilis in children, two or three baths a week being given, each containing from eight to forty-five grains of the bichloride, according to the age of the child. Special emphasis is laid upon the inunction treatment of syphilis, some forty-five grains of blue ointment being rubbed each day into the non-hairy parts of the body. Thirty to sixty rubbings are about as many as can be prudently employed in one series, and then they should be stopped for a while, some preparation of iodine being taken meanwhile. The oleate of mercury is not so active as the blue ointment. The mercurial soaps of Fanta, Unna, and Oberländer form excellent substitutes for the mercurial ointment and act very promptly. The treatment by hypodermic injection has been tried by him, the various proposed solutions having been employed from time to time. It is a valuable method where the physician wishes to have complete control of the treatment, but does not take the place of the older methods. The treatment by one or other form

of mercury should be continued until the symptoms of the disease have disappeared, and should be thoroughly carried out. The iodides are regarded as rendering good service after a thorough course of mercury. The iodides of potassium, ammonium, and iron are those specially useful. The "mixed treatment," so called, is not considered favorably; better results are to be obtained by the separate administration of the drugs. But space will not permit us to go further in abstracting from this practical little work, and we will take only enough to give the author's two summaries, as follows:

Summary of the use of mercury.—a. The most reliable preparation and the most lasting in its effects is the blue ointment, which should be used, where possible, from the beginning of the treatment. *b.* The subcutaneous injection of mercury is next in reliability, but must be used with caution. The least soluble preparation should be used when there are gummatous or ulcerative processes to combat, or an energetic treatment is necessary on account of parenchymatous syphilitic affections. In the slighter forms of syphilis the more soluble preparations may be used. *c.* The mercurial soap and Unna's mercurial plaster-muslin are very useful, as is also the tannate of mercury. *d.* As a preparatory course for the use of the stronger preparations of mercury, the bichloride of mercury may be given in pill or solution. *e.* As intercurrent medication, between two courses of either inunctions or hypodermic medications, the protiodide of mercury should be used. *f.* The constitution of the patient should guide us in the choice of our remedies, whether we shall use a stronger or a weaker preparation or dose.

Summary of the general treatment of syphilis.—1. Syphilis is a chronic disease, and requires a long-continued course of treatment. 2. Mercurial treatment should be commenced as early as possible in cases with marked onset; in slighter forms somewhat later. 3. Mercurial treatment should be continued for two or three months. Then the iodide should be given for two months. 4. After four or five months' unbroken treatment, a pause of two or three months should be made. Any local lesions should be treated by local treatment. 5. In relapses the same course of treatment should be followed, only of shorter duration, say three months; if no relapse occurs within the first six months after the beginning of treatment, the second course can be deferred until the eighth to the tenth month, reckoned from the beginning of the disease. 6. The treatment with decoctions is to be employed in diseases of parenchymatous organs if such do not yield to a second course of mercury and iodides. 7 and 8. Balneotherapy and hydropathy are useful at times as final methods of treatment. 9. If the disease continues into the second year, in spite of treatment, a two-to-three-months' course of mercury and iodide is to be gone through with, or one of greater duration if marriage is proposed. 10. Generally speaking, after a year and a half to two years of well-directed and early-begun treatment, the result will be highly satisfactory.

THE MICROBES OF PYÆMIA AND SEPTICÆMIA.—In the St. Petersburg Alexander Hospital, Dr. L. Besser has made numerous cultivations of microbes taken both from the blood and pus of living persons and bodies of the dead, with the object of determining which of the various microbes are the cause of the disease. In the first case he examined 23 cases of pyæmia in part following typhoid and part traumatic. Among these he found, on the living, microbes in the pus twenty times; in the blood out of 12 cases eleven times; and in the serous fluid two times. In pus from the cadaver he obtained positive results seventeen times. In the blood of 14 cases nine times, as well as in various organs. As regards the species of microbes, in 8 cases staphylococci were met with, in 14 cases streptococci, and in 1 case both kinds. He draws the conclusion that pyæmia is a result of invasion of the system by micro-organisms, that either the staphylococcus or the streptococcus may be the offender, and that these are identical with those generally met with in abscess. He also investigated 22 cases of septicæmia, all of traumatic origin. In the whole, streptococci were met either in the blood or pus. In 4 cases he found them in blood during life, but in 12 others his search was not successful. In 15 cases *post mortem* he only found them in the blood in 7; but in 18 cases in which the organs were examined he discovered them in 16. The urine was further tested in 4 cases, with a positive result in 3. From these investigations the author draws the not unnatural conclusion that in septicæmia it is the streptococcus alone that is at fault.—*The Medical Press.*

EFFECT OF GALVANO-PUNCTURE ON THE SAC OF AN AORTIC ANEURISM.—At a late meeting of the Pathological Society of London (*The British Medical Journal*, November 24, 1888), Dr. Ralfe exhibited a specimen, showing the effect of galvano-puncture on the sac of an aortic aneurism. The patient was admitted under Dr. Ralfe's care in September, 1887, into the London Hospital, and died in August, 1888. When admitted, the aneurism had already made its way through the cartilages attached to the sternum, and the skin was already assuming a deep livid hue, while the pulsation was extreme. It was considered that the aneurism would shortly rupture externally. To relieve the extreme pulsation, Dr. Ralfe suggested galvano-puncture, which was performed by Mr. Mansell Moullin. Improvement followed the operation, the swelling subsided and became harder, and the skin lost its livid hue. This improvement lasted some time, but presently the pulsation returned, and the patient was troubled with a violent paroxysmal cough. Galvano-puncture was again resorted to, and again the pulsation diminished and the tumor became harder, while the cough disappeared. In all, galvano-puncture was resorted to thirteen times, and always had the effect of giving relief to the patient. Finally, after nine months of treatment, a pustule appeared over the seat of an old puncture, and from that time adhesion took place between the skin and the tumor, and perforation slowly ensued; but, instead of a violent hemorrhage, comparatively slow oozing took place, and the patient gradually sank from weakness, without experiencing shock or pain. Dr. Ralfe claimed for galvano-puncture, in suitable cases, (*a*) prolongation of life in rapidly progressive cases; (*b*) relief of pain, undue pulsation, and of paroxysmal cough; (*c*) the probability of an almost painless death, owing to the slow oozing from the thickened sac, instead of sudden rupture, which, if it occurred internally, must be for a short while extremely painful.

DIFFERENCES BETWEEN CHILDREN AND ADULTS IN REGARD TO MORBID ACTION, AND THE EFFECTS OF TREATMENT.—From a recent address by Dr. W. H. Dickinson (*The Lancet*, November 3, 1888) we take the following conclusions: Children differ from grown people in their greater susceptibility both to exhaustive and recuperative influences. Such of their diseases as are of the nature of growths partake of the rate of progress which belongs to the period of development. This applies to the fibroses as well as to isolated tumors, though the fibroses are far more infrequent than afterward. Many inflammatory disorders, particularly of the brain, are more common in childhood than later, but with regard to many inflammations the power of recovery is greater. Those of the lungs are more frequent and cause more deaths, but in the individual the prospect is better. Acute rheumatism is comparatively infrequent, but when it occurs it brings greater danger to the heart. Some febrile complaints are more frequent, and some less so than afterward, but, as a rule, their proportionate mortality is less. There are special differences in the action of drugs, the most important of which is the greater influence of alcohol for good and evil. Finally, children respond to treatment, as they often succumb to disease, more readily than do older patients, so that with them our responsibility is the greater.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 19, 1889.

OUR CITY'S MEDICAL CHARITIES.

THE city of New York has nearly 14,000 persons under the charge of its Commissioners of Charities and Correction. During the course of a year, between 30,000 and 40,000 persons come under their control. Most of them are sick, injured, or insane. The humane and skilful supervision of this vast number of the suffering is no easy matter. In a city like ours, in which politics is the first and fitness the second consideration in determining the selection of officers, the grossest abuses have at times existed. Improvements, however, have steadily been made, and although in many cases the special system is too vicious ever to be made really satisfactory, yet there is promise of better management each year.

One of the most useful agencies in promoting reforms in this field has been the Visiting Committee for Bellevue Hospital and other public institutions; a committee which works under the auspices of the State Charities Aid Association. Each year a report is published which has, almost without exception, shown the results of intelligent and conscientious examination of the city's various medical charities.

The last report, for the year 1888, contains a number of interesting criticisms. The city lunatic asylums have always come in for a large share of complaints. Every year the number of lunatics admitted exceeds by one or two hundred the number discharged. The result is a steady accumulation of pauper lunatics. Even assuming that our city population increases at the rate of 40,000 to 50,000 annually, the proportionate increase of lunatics is twice what it ought to be.

One of the worst institutions under the control of the Department of Charities and Correction is the Workhouse. It is to this place that "ten-day" offenders, the drunk, the destitute, and old "rounders" are sent. Nearly 25,000 people are sent up by the courts and city authorities during the year, the majority of the women, at least, being old offenders. The hospital for the accommodation of the sick in this floating population of nearly 3,000 has just fifty-six beds, and there are very often twice as many patients.

The Maternity Service of Charity Hospital presents a most creditable record. In the past year there were 349 confinements, with 3 deaths of mothers, or $\frac{8.6}{100}$ per cent.; 13 babies died, and there were 27 still-births.

Perhaps the most unpleasant showing of all is that of the Infants' and Children's Hospitals on Randall's Island. These institutions, which are under the charge of the same medical officers, in 1887 treated 1,679 patients. In the Infants' Hospital the simple record is: "Cared for during the year, 975; died, 356." The infants who are admitted without the mother are known as "orphan babies." Among this class the mortality is frightful, and was even greater in 1888 than in 1886 or 1887. Among 534 orphan babies, 325, or over sixty per cent., died. It is stated that only one "orphan baby" admitted to the Hospital in the past eighteen months has reached the age of one year. The Babies' Hospital on Randall's Island is plainly no health-resort.

In conclusion the Committee says of Bellevue Hospital: "The repairs and improvements at Bellevue Hospital are not altogether matter for congratulation, for the unfitness of the building for hospital purposes, its defective ventilation and construction, can never be wholly done away. Nearly fifteen years ago, a special committee of the State Charities Aid Association made a report setting forth reasons for the reconstruction of the hospital, and offering to furnish plans for the same. We regret that this measure has not been persistently urged upon successive Boards of Commissioners; if all the money expended in patching up the Hospital for the past fourteen years had been used to rebuild it, we might now have a new Bellevue, built on scientific principles."

We can hardly agree with this opinion. The Hospital is massively built, and can be now thoroughly and scientifically ventilated. Asepsis, which is the main thing, is possible in any hospital, and has been attained in Bellevue. No better work in surgery is recorded in the most scientifically constructed hospitals than is being done at this institution now.

CHILDBEARING AND THE PROCESSES OF NUTRITION.

THE puerperium is usually regarded as including only the period from the birth of the child to the establishment of a normal condition of the generative organs, *i.e.*, six to eight weeks. French writers, notably Tarnier and Monneret, make it include the whole period from conception to the reappearance of the menses, or even the end of lactation. Auvard divides this time into (1) the puerperality of gestation, (2) of parturition, (3) of regression, (4) of lactation. Such an extension of the word puerperium is unnecessary, confusing, and without etymological justification; but the division itself is convenient, and affords M. Auvard an opportunity (*Gazette des Hôpitaux*) to present concisely some facts regarding the relation of these periods to nutrition, and especially to obesity.

Nutrition, says Auvard, didactically, is composed of four successive acts: Absorption, assimilation, disassimilation, and elimination. Here M. Auvard is more concise than correct, for he does not allow for the influence of that part of the food which, with very little change, is broken up and rushed through the kidneys as urea. However, not to be too critical, Auvard's classification is doubtless sufficient for his purpose at hand. During childbearing, according to Auvard, and no one will dispute him, there is a general slowing of nutrition. Absorption is less active, as shown by anorexia and vomiting; assimilation is

slower, as shown by anæmia and a greater tendency to scrofula and phthisis. The imperfect disassimilation tends to obesity, biliary lithiasis, and osteomalacia. Of all these, Auvard believes that obesity is the condition most surely promoted by gestation. The process of elimination is also lessened during gestation; at least, so far as the kidneys, and perhaps the skin, are concerned.

The urine, according to Tarnier, increases in amount at first, but the solids excreted decrease, excepting only the chlorides. "Puerperal eclampsia is the grave in which the inactive emunctories bury their bad work."

The period of parturition is too short in itself to modify especially nutrition; but the subsequent period, that of puerperal regression, is one in which all the nutritive processes are more active. The quantity and density of urine augments, the body-weight falls about ten pounds, and the *gravis odor puerperii* appears as a result of the over-active cutaneous elimination. When regression is finished, the lactation-period proper may be said to have begun. During this time absorption and elimination are very active, but it is claimed that assimilation and disassimilation are slow. There is now a predisposition to anæmia, and, in some persons, to tuberculosis.

The various changes above indicated are not, as a rule, very marked, and are not often pathological. The "tachyatrophy" and "bradyatrophy," as they have been called, are physiological adjustments of the woman to the new conditions.

The general effect upon women of childbearing is no doubt to promote the development of obesity in greater or less degree. This depends, however, somewhat on race and condition in life. The obesity from childbearing can be kept off by self-denial as regards food, and indulgence as regards exercise.

COCAINE-CHLOROFORM NARCOSIS.

The majority of surgeons still employ a simple form of anæsthesia, *i.e.*, they use either chloroform or ether alone. For special operations a preliminary injection of morphine is used. But the preliminary injection of atropia, cocaine, or the administration of bromide, is probably nowhere systematically adopted. There is a disposition, however, to make surgical anæsthesia a more complex affair than has usually been done; and this tendency is strongly favored by Professor Obolinski, of Cracow, who comes forward (*Wien. med. Wochenschr.*, Jahr 1., Nos. 15 and 16) with a "new method of mixed narcosis."

This consists essentially in the combined use of cocaine and chloroform. Obolinski injects, either before or after the anæsthesia is obtained, from one to three centigrammes of cocaine; or he injects in the neighborhood of the seat of operation, and during its progress, from three to seven centigrammes. Cocaine is used, on the ground that it is a complete antagonist of chloroform and chloral. This, however, is not strictly true, for cocaine is rather a general exciter of the central nervous gray matter than a direct and powerful stimulator of the heart, while its stimulant effect upon respiration is not to be depended upon.

Obolinski claims, however, that this mixed narcosis is an advantage, because it secures anæsthesia with the use of less chloroform. Here, too, it may be said that partial chloroform narcosis may be more dangerous than if a full amount were obtained.

It is further claimed that vomiting is prevented by the cocaine-chloroform narcosis, and that the patients have few disagreeable after-effects.

CIGARETTE-SMOKING BY BOYS.

"The only serious harm that I have seen from smoking tobacco has been caused through the smoking of cigarettes by boys," is an observation made recently by a physician of large experience in this city. We occasionally receive communications which confirm this opinion, and show that the habit of cigarette-smoking among boys is becoming more common and is working most pernicious effects. The rivalry among cigarette-makers is now so great that prizes are offered to those who smoke the most. Unfortunately, the prizes are usually of the cheap and gaudy character that appeals most to boyish tastes; and, in fact, it is affirmed that boys are the chief prize-winners. There should be some law or ordinance forbidding the sale of cigarettes to boys. As matters are going now, cigarette-making rivals the liquor-trade in its pernicious influence upon the rising generation.

THE BEST TWENTY-FIVE DRUGS.

Our esteemed contemporary, *The American Practitioner*, has discussed with its usual intelligence and acumen, the editorial published in The Medical Record, some weeks ago, upon the question "Is the Practice of Medicine a Failure?" Our contemporary objects to the exclusion of surgery and hygiene from the practice of medicine, and its objection is, of course, to a certain extent, valid; for the general practitioner includes both these branches in his work. Our inquiry was, however, directed more especially as to the utility of medical intervention in the course of acute and chronic disease. We intimated that we did not take a pessimistic view of this subject, but rather the contrary. Still, it is apparent that medicinal treatment is not efficient in any degree proportionate to the amount of medication, the extraordinary number of our drugs, or the immense industry bestowed on our materia medica.

It is quite probable, indeed, that with twenty-five drugs the medical art could be carried on with just as much, if not more, success. Some people with idiosyncrasies or unusual fastidiousness might suffer; but this could be more than supplemented by a diminution in excessive and dangerous dosing.

It would be interesting to learn from practising physicians what the twenty-five best drugs are. We assert, confidently, that twenty-five is a minimum number, and that the bumptious heretics who, in days of old, claimed that three drugs—opium, mercury, and potash—were enough, knew neither the science or practice of medicine.

The following list has been suggested to us as representing the soul of the Pharmacopœia: 1, opium; 2, mercury; 3, iodides; 4, quinine; 5, chloroform; 6, ether; 7, sulphate of magnesia; 8, salicylic acid; 9, aloes; 10, alcohol; 11, bromides; 12, iron; 13, chloral; 14, castor-oil; 15, digitalis; 16, arsenic; 17, colchicum; 18, ipecac; 19, aconite; 20, strychnia; 21, cocaine; 22, ergot; 23, bicarbonate of potash; 24, mineral acids; 25, nitrites.

Pepsin is a widely used remedy, but it can hardly be regarded as a drug, and it is very possible that, on the whole, it does more harm than good by pandering to a weakness rather than attacking its roots. Iron is another remedy whose value, except as a mineral food, is problematical.

Naturally, the best twenty-five drugs will differ somewhat in accordance with climate and prevalent diseases; but we should say that the foregoing list was a fairly correct one.

THE MINERAL WATERS OF THE YELLOWSTONE PARK.

EVERYONE familiar with European watering-places and their American equivalents knows, and many doubtless regret, the great superiority of the transatlantic over our own sanitary resorts. Yet no one will contend that nature has been partial to the older country in bestowing her favors. It is simply an affair of human development, our own resources having been as yet subjected but slightly to the modifying effects of intelligent enterprise.

The Yellowstone Park affords a good illustration of this neglect on our part to improve upon great natural advantages. Physicians who have visited that extraordinary tract of land have been struck by the abundance and variety of its mineral springs; but until quite recently reliable information concerning this multitude of hot and cold springs was not obtainable.

From the current issue of the *Epoch* we learn, however, that a step in the right direction has now been taken. It appears that in Bulletin No. 47 of the Geological Survey the first official instalment of reliable information has been published. The report in question contains analyses of forty-three of the more noteworthy and typical waters of the Yellowstone Park, together with a full account of the analytical methods employed. The analyses were made by Professor F. A. Gooch and J. E. Whitfield, in the laboratory of the Survey at Washington, a fact which will vouch for their accuracy.

The temperature of the Yellowstone Park springs shows a wide range from great cold up to the boiling point. As for mineral ingredients, there is also considerable variety. Astringent waters, carbonated saline springs, highly siliceous waters, lithiated and arseniated waters, and many others are found in abundance. The Devil's Ink Pot, near Mount Washburn, a nearly boiling spring, is said to be unique among mineral waters. It contains, along with other ingredients, nearly forty-eight grains of ammonium sulphate in every quart. It is notable for its contents in free sulphuric, hydrochloric, and boric acid, and it carries appreciable quantities of lithia, of alum, and of sulphuretted hydrogen.

Continuing, the *Epoch* says that—

"Among the geysers and hot springs generally there seems to be a good deal of a family likeness. As mineral waters go, they are not very heavily charged with mineral matter; carrying, as a rule, less than two grammes of dissolved solids to the litre, or under 120 grains to the gallon. The Chrome Spring reaches nearly three grammes, however, and the Devil's Ink Pot, the extreme case in the present series, has three and four-tenths approximately. The waters of Ballston and Saratoga range from four to six times as strong, while many of the most noted Virginia Springs are much weaker.

"All of the Park waters are, relatively to their total contents, decidedly siliceous; and to their deposition of dissolved silica the curious geyserite formations are due. Most of them contain definite amounts of borax, nearly everyone contains lithia, and in almost every hot water there are very perceptible quantities of arsenic. The latter element is more abundant in several foreign waters of high repute, but the proportions found in the geysers are not to be despised. Iodine seems to be universally absent, and bromine is only found in a few cases in very small amounts. Neither are sulphur waters conspicuous in the list of waters analyzed. The remaining constituents of the geyser waters are the almost universally diffused sulphates, carbonates, and chlorides of lime, magnesia, and the alkalies. None of them are notably chalybeate."

The precise indications for the employment of these various waters of course remain to be determined by clinical observation. From what has just been published, it would appear that the springs will be found useful in the shape of baths rather than as beverages.

In any event, it is safe to say that the Yellowstone National Park will, in course of time, become as well known for its sanitary advantages as for the marvellous scenery and imposing natural formations in which it abounds.

News of the Week.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—In addition to the papers already announced, the following have been promised for the meeting of the New York Medical Society, beginning in Albany on Tuesday, February 5, 1889, at 10 A.M.: "The Treatment of the so-called Perityphlitic Abscesses," by Robert F. Weir; "Basedow's Disease," by H. R. Hopkins; "Cranial Measurements in Twenty Cases of Infantile Cerebral Hemiplegia," by Edward D. Fisher and Frederick Peterson; "Cases Illustrating the Curative Effect of Convex Glasses in the Strabismus of Young Children." "On Some of the Minor Types of Pneumonia," by T. E. Satterthwaite; "The Practical Application of Acoustics to the Physical Signs of the Human Chest in Diagnosis," by J. R. Leaming; "The Importance of the Early Recognition of Cancer of the Cervix Uteri," by Henry C. Coe; "Office Photography with the Flash Light," by Henry G. Piffard; "Inferior Dental Neurectomy," by J. H. Glass; "Vaginal Hysterectomy," by James B. Hunter; "Septic Poisoning in Early Life," by Henry D. Chapin; "Amblyopia in Diabetes," by W. O. Moore. Gentlemen who propose to discuss any of these papers will confer a favor on the Business Committee by sending their names to Dr. Roosa, 20 East Thirtieth Street, New York, without delay.

LIVING WITHOUT KIDNEYS.—A curious story, which is characterized by our English exchanges as decidedly "American," comes from Philadelphia (*Medical Register*). A patient suffered from disease of the right kidney, which, together with the spleen, was removed by laparotomy. After these two organs had been removed, it was found that he had no other kidney. When the effect of the ether had passed away, the patient went into convulsions and partial unconsciousness, death being momen-

tarily expected. Days passed and ran into weeks, and there was no change, and at the end of a month the patient was still alive, and appeared to have an excellent prospect of recovery. How it is that the patient lived is a mystery, and it is suggested that the removal of the spleen, the use of which is unknown (?), was perhaps the proper thing to do. The functions of the kidneys are now said to be performed by the skin, the respiration is reported to be "almost double" the normal amount, and the "water fairly drips from the skin." A number of other curious details are given, such as the growth of hair on a previously bald head.

THE HOSPITAL COLLECTIONS up to the 16th inst. had reached the sum of $38,000.

THE CHILD'S NURSERY AND HOSPITAL realized this year about $19,000 from the Charity Ball.

DR. WALTER WYMAN is in charge of the U. S. Marine Hospital Service during the sixty days leave granted to Dr. Hamilton.

DR. JOSEPH L. BODINE, of Trenton, N. J., died on January 2d, in the forty-ninth year of his age.

SPECTACLE MISSIONS.—Dr. Edward J. Waring has conceived the idea of establishing "Spectacle Missions," or societies for the gratuitous distribution of spectacles among the poor. We are told that $45 will cover the cost of 240 pairs of spectacles and 240 New Testaments. This estimate shows the modest margin of profit which ordinarily enures to our esteemed allies, the opticians.

THE DEATH OF DR. WILLIAM J. WELCH, of this city, occurred on January 14th. Dr. Welch was born in 1847, and graduated from the University Medical College in 1866.

THE MARINE HOSPITAL SERVICE.—The bill reorganizing the Marine Hospital Service has become a law. The essential feature of this new law is that appointments to the service are made by the President and confirmed by the Senate. The service is now, therefore, upon the same non-political footing as that of the Army and Navy. Changes in politics can no longer endanger the position or prospects of advancement of its members. In accordance with the law, the President has sent to the Senate a list of names of all the present members of the service for appointment as Surgeons, Assistant Surgeons, and Passed Assistant Surgeons, respectively. Dr. Hamilton has crowned his labors for the promotion of the service in a way which must be most gratifying as it is creditable to him.

THERE ARE RUMORS that Philadelphia is to have a new medical college, eclectic in character, which is to be called "The Burton Medical College." We trust that our neighbor city will be spared the infliction. The eclectic colleges, so-called, of this city have been pests of a most incurable kind.

A CHARGE AGAINST FAMILY PHYSICIANS.—It is one of the notable facts in the history of medicine, that the charge of immorality has never been more than incidentally and sporadically made against physicians. In the satirical, dramatic, and other literature, in which the foibles and weaknesses of medical men are set forth, immorality is not classed among their vices. The priesthood has won an unenviable conspicuousness in this respect. A clergyman of Brunswick, N. J., however, during the course of a sermon preached recently, read a letter from a brother minister of this city, in which he stated that many fallen women who had been reclaimed by the Florence Mission attributed their ruin to their family physician. The publication of bald statements of such a character is likely to do gross injustice to medical men. There are doubtless some black sheep among us; but, taken as a whole, there is no class of men so scrupulous in their conduct toward the women with whom they are brought into relations. To such conduct they are bound, not only by the solemn oath of graduation, and by their sense of personal and professional honor, but also by the absolute need which a family physician has of keeping his name unsmirched.

IT IS REPORTED that the Royal College of Surgeons has voted almost unanimously to censure Sir Morell Mackenzie for the publication of his account of the case of the Emperor Frederick. The resolution, it is said, was passed despite the fact that the Empress Victoria used her personal influence to prevent the vote.

HONOR TO PROFESSOR LEIDY.—The Cuvier Prize of the French Academy of Sciences, which is awarded triennially for the most important researches in the domain of general natural history and geology, and which has associated with it, among others, the names of Von Baer, Ehrenberg, Richard Owen, Agassiz, and Heer, has been this year decreed to Dr. Joseph Leidy, Professor of Anatomy in the University of Pennsylvania, and President of the Academy of Natural Sciences of Philadelphia.

RECEPTION TO DR. WILLIAM GOODELL, OF PHILADELPHIA.—One of the events of the season was the reception tendered by Dr. Paul F. Mundé to Dr. William Goodell, of Philadelphia. A large number of medical gentlemen from this and other cities were present to do honor to the distinguished guest.

MAN'S WORST ENEMY.—"The bacillus of tubercle is," say MM. Filleau and Léon Petit, "of all micro-organisms, one of the most refractory to the action of the most destructive agencies. It maintains its virulence after lying for forty days in putrid sputum, and for one hundred and eighty-six days away from contact with air. It can live at temperatures between 86° and 104° F. The most unfavorable conditions, though affecting its activity, do not compromise its existence, for it resumes its virulence whenever its surroundings become suitable. To render it inactive, it is necessary to have recourse to violent means, such as ebullition, steaming, or prolonged contact with antiseptic substances, such as ammonia, concentrated salicylic acid, absolute alcohol, or a strong solution of carbolic acid. Corrosive sublimate itself is powerless to disinfect the sputum (Schill and Fischer). The bacillus acclimatizes itself amid the most unfavorable surroundings. It complies with the exigencies of its condition, and even alters its shape, but without losing any of its virulence, of which it gives ample evidence whenever fortune favors it. Its polymorphism is not the least curious point in the life-history of this organism. Thus it is sometimes a short rod, sometimes a line—occasionally it splits, and forms spores—but it always returns to the bacillus in its complete form, with its virulence intact, whenever circumstances become favorable. 'It knows how to suffer, but it never loses sight of its claims.'"

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 7, 1888.

A. BRAYTON BALL, M.D., IN THE CHAIR.

DR. BEVERLEY ROBINSON presented a patient with

HYDRO-PNEUMO-THORAX.

T. McQ——, twenty-four years of age, an Englishman, had enjoyed fair health up to the beginning of his present trouble. One evening while intoxicated he quarrelled with some companions, and was choked and pushed with some violence against a wall. The following morning he complained of pain in the left chest. Nine weeks later he entered St. Luke's Hospital, and was there found to be suffering from hydro-pneumo-thorax. The left chest contained air and fluid, and the heart was pushed over to the right, the apex-beat being near the mammary line on this side. Thoracentesis was performed and twenty ounces of fluid, but no air, withdrawn. The operation was repeated later, when, after the withdrawal of about one ounce of fluid, a large amount of air escaped. The fluid then appeared again in the aspirator, but after about three ounces had been removed the signs of weak heart became so alarming that it was necessary to suspend the operation. The chest was now full of fluid but contained no air; the succussion-sound which was before heard could not now be elicited, and percussion gave no evidence of anything but fluid. The heart was still on the right side, and had not moved any toward the left at the time of the first operation. It was possible that it was a case of congenital dextrocardia, though the other viscera were not transposed.

The first point of interest in the case was concerning the origin of the hydro-pneumo-thorax. Three hypotheses had been suggested: 1. That there had been a fracture of a rib, tearing the pleura and penetrating the lung. Against this theory, however, was the fact that the physician in attendance at the beginning of the trouble found no fracture, and also that there were now no evidences of such an accident having occurred. 2. That perforation of the pleura had occurred as a result of tubercular disease of the lung. But the previous history of the patient did not point to any pulmonary trouble prior to the receipt of the injury. 3. That rupture had occurred as a direct result of the traumatism caused by choking and simultaneous compression of the chest when the man was squeezed against the wall. This, the speaker thought, was the most probable theory.

Another point was as to the cause of the alarming heart-symptoms at the time of the second thoracentesis, compelling the operator to desist from the attempt to withdraw any more fluid. It was improbable that fright was the cause, for the man was a plucky fellow and had not seemed to be at all alarmed either at this operation or at the preceding one. Dr. Robinson's theory was that the opening into the lung had closed before the second operation, and that the withdrawal of such a large amount of gas had caused a vacuum which the compressed lung could not fill. The pericardium, assuming that the heart was displaced by the air and fluid in the left chest, had contracted adhesions in its new situation, and the dragging upon it produced by the partial vacuum in the now closed pleural cavity had caused serious disturbance of the heart's action. If this were the case, it became a very serious problem what to do for the patient's relief. His condition was now a precarious one, and he was in danger of sudden death from heart failure, yet any further attempts to withdraw the fluid and thus bring back the heart to its normal situation seemed likely to be attended with very grave risks. The speaker intended, however, to make the attempt, stimulating the patient freely and proceeding very cautiously and deliberately in the withdrawal of the fluid. It was a curious fact that, whereas formerly the patient had suffered much from dyspnœa, he now had no unusual shortness of breath, and could even ascend the stairs without difficulty.

The third point in connection with the case which was of interest was that the fluid was still serous; for it is extremely rare to find fluid which has remained in the chest, in a case of pneumo-thorax, for several weeks without becoming purulent. Finally, it is supposed by some authorities that an effusion of fluid into the pleural cavity causes great pressure on the lung, but at the first operation there was no escape whatever of air, thus showing that there was no great degree of pressure.

DR. G. L. PEABODY said that he was at a loss to explain the origin of the disease. He had recently had two patients with pneumo-thorax resulting from the rupture of an emphysematous lung. A very puzzling feature in this case was that there should be such a free entrance of air into the pleural cavity without suppuration of the contained fluid.

DR. ROBERT F. WEIR said that he had seen two cases of rupture of the lung from violence—hæmo-thorax. The patients died, but at the autopsy no pus was found in the pleural cavity. The air in the deeper portions, that is, near the surface of the lungs, is so pure that the danger of suppuration in a fluid exposed to it is very slight. When perforation of the pleura occurs from disease the case is different, but in a traumatic rupture of a previously healthy lung he would not expect to find the fluid purulent.

DR. A. B. BALL thought that the explanation of the alarming heart-symptoms by the production of a vacuum in the left chest cavity was the correct one. The opening might have been a very small one, and have thus closed spontaneously. Even a small opening will allow a pretty free escape of air.

DR. ROBINSON said that he intended to try again to remove the fluid, for that was the only way to get the heart back again in its proper position, yet he feared a recurrence of the alarming symptoms which had forced him to stop at the last operation. He had thought of introducing sterilized air, but there were many difficulties in the way of carrying out this procedure.

DR. JAMES B. HUNTER then read the paper of the evening (see p. 57), entitled

THE MENOPAUSE.

DR. ANDREW H. SMITH said that he had not noticed in the enumeration of causes which may hasten the occurrence of the menopause any reference to psychic disturbance. This is sometimes a very potent factor. He recalled the case of a lady, thirty-six years of age, who was greatly alarmed one night by a fire. She recovered from her fright, but never menstruated again. Referring to the instances in which the menopause is delayed in consequence of pathological conditions, and when hemorrhage occurs regularly from this cause, he inquired whether Dr. Hunter believed that ovulation took place also in such cases.

DR. HUNTER replied that he could not say whether ovulation occurred in such cases or not. There were several cases on record of pregnancy in advanced age, and Tilt had reported a case occurring in a woman ninety-two years of age. If there was a regular appearance in the flow he should be inclined to regard it as true menstruation, even if it did occur at an age beyond that at which the menopause usually took place, and in such a case pregnancy was possible.

DR. CLEMENT CLEVELAND reported a case of

PYO-NEPHROSIS,

occurring in a woman, twenty-nine years of age, who had been sent to the Cancer Hospital as a case of malignant disease. The tumor was on the left side, and was distinctly fluctuating, and the diagnosis lay between an ovarian tu-

mor and abscess of the kidney. The day before the operation, however, the woman passed a large amount of greenish pus in the urine, and the operation itself showed that the affection was an abscess of the kidney. A trocar was introduced through the abdominal opening, and more of the greenish pus, such as was passed in the urine, was withdrawn. At the bottom of the wound, and a little to the left of the centre, was seen a large mass which the operator took to be a portion of the enlarged kidney. This, he supposed, would eventually atrophy and disappear.

Dr. R. F. Weir said that the case was interesting from a surgical point of view. It was usually thought improper to open the kidney from the abdominal cavity. Sometimes in those cases of pyo-nephrosis the cause of the trouble was discovered to be a stone, and in such a case it would be found difficult to remove it through the sinus.

Dr. William T. Bull exhibited a small, portable storage battery for furnishing an electric light. The battery could be charged with a dynamo, and when so charged would run for five hours.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNECOLOGY.

Stated Meeting, December 27, 1888.

J. E. Janvrin, M.D., Chairman.

EXHIBITION OF A PERINEAL RETRACTOR FOR THE DORSAL POSITION, WITH AN ELEVATOR FOR THE ANTERIOR VAGINAL WALL.

Dr. A. H. Goelet presented the instruments, which were especially adapted to use in the application of electricity to the uterus and vagina. The retractor was a speculum of the general shape of S, cast thin, and coated with hard rubber for insulation. It was to be held in the left hand of the operator, the patient in the dorsal posture, and the elevator of the anterior vaginal wall held in the left hand by the nurse as she stood to the right of the patient. The elevator being made of hard rubber, yielded sufficiently to obviate pain to the patient. By the use of these instruments space was allowed at the vulva for the introduction of an electrode of considerable size. Two hundred milliampères had been employed with safety. While intended for the dorsal position, they could be employed with the patient in the Sims position. Their advantage was due to ordinary methods not permitting sufficient expansion of the vulva for the use of suitable electrodes, or those carrying a strong current. He also exhibited the electrodes which he was accustomed to use.

Dr. E. H. Grandin thought the instruments were the result of ingenuity, but personally he had never found it essential to use a speculum of any kind in order to apply electricity within the vagina or uterus. Indeed, he thought such instruments tended to complicate a method of treatment which was one of the most valuable at the physician's disposal in certain pelvic affections. He did not require a nurse to elevate the anterior vaginal wall, nor did he engage his left hand in depressing the perineum. It was all-important that the general practitioner, who ought to employ this remedy if it was to be of wide value, should not find the methods of application complicated.

Dr. Charles Jewett used the Sims speculum in Sims position while galvanizing the uterus. The patient held the cotton pad or Apostoli electrode. The advantage of this position was that it enabled him to thoroughly disinfect the parts, which he considered necessary for successful treatment. He had had no difficulty in introducing the ball-electrode into the vagina.

Dr. H. T. Hanks thought the instruments exhibited would prove useful in general examinations for diagnostic purposes, when the physician had a large dispensary service, time limited, and the patient had, as she usually did, assumed the dorsal position. He had not found a speculum necessary when applying electricity.

Dr. Goelet asked Dr. Grandin how many milliampères he could use with the chamois-covered electrode without cauterizing the vagina, if no speculum were employed. He sprayed the vagina thoroughly, and wiped it out several times with absorbent cotton, which further necessitated a speculum.

Dr. Grandin remarked that he had employed electricity probably as much as any physician in the city the past three years, but had never, in using it as described, cauterized the vagina. The strength of the current was from 40 to 75 milliampères; 150 to 200 was altogether higher than necessary. He did not think it necessary to spray or wipe out the vagina before introducing the electrode, unless there were excessive leucorrhœa. Septic endometritis or salpingitis had never resulted for want of asepticism in his cases.

Dr. J. P. Tuttle then read the history of a

CASE OF EXTRA-UTERINE PREGNANCY, IN WHICH THE FŒTUS WAS DELIVERED INTACT PER RECTUM.

The mother, aged thirty-five, married eleven years, with tubercular family history, had never been pregnant prior to this illness. She had been troubled for years with possible falling of the womb, and had been treated by regular and irregular physicians.

When Dr. Tuttle saw the patient in March, he learned that her menstrual periods in January and February had been shorter than usual. Digital examination revealed the womb well down, retroverted, somewhat enlarged, but the use of the sound for positive diagnosis was refrained from on account of possibility of pregnancy. Two days later pain, referred to the rectum, was relieved by cold applications, but the patient refused to take an anæsthetic and submit to a thorough examination. Extra-uterine pregnancy was thought possible. The idea of pregnancy, however, was little entertained by the patient, who passed into the hands of an electro-therapeutist. Dr. Tuttle saw her again in April, and learned that during one of the electric séances, at which the electrode was introduced into the uterus, she had a severe hemorrhage, lasting two hours, and was shown a black mass which the doctor said he had removed from the womb, and which had been the cause of all her trouble. She passed blood for more than six days afterward, and Dr. Tuttle was of the opinion abortion had been produced. Examination of the patient two days later, or April 25th, revealed continued vaginal heat and tenderness about the peri-uterine tissues; the depth of the uterus was five inches, it was slightly movable, in fair position, but there was a large mass between the womb and rectum, closely attached to the womb, and movable with it. It felt like a fibroid or possible hæmatoma. Under general treatment for some weeks the patient got up, was able to remove to another part of the city, and attend to household duties, although contrary to instructions. June 1st it was stated she had continued to have slight flow of blood for eight weeks. The lining membrane of the uterus was smooth. The tumor seemed not to have grown larger, but had sunk lower down, giving rise to certain painful symptoms. Persulphate of iron in solution was thrown into the uterus to stop hemorrhage, which had ceased by June 13th. On June 25th it was noted the tumor had sunken much lower and felt softer; there was pain in the rectum and difficulty at stool. He was called the next day, and on his arrival found another doctor had got there first, and was removing a four months' fœtus from the rectum. The patient had, the night before, taken a cathartic, and during its action was seized with severe pain, and expelled the fœtus through a clean rent in the rectum about three inches in length. The cord was attached to both child and placenta. The latter was firmly adherent, and slight traction on the cord bringing on arterial hemorrhage. It was allowed to remain and a tampon was introduced.

The patient survived partial collapse. About two days later he attempted again to remove the placenta, and found it very tightly wedged in the rectal wound. Slight traction upon it brought on hemorrhage, and so severe shock that death seemed imminent. There was no evidence of peritonitis. About the fourth day after the expulsion of the fœtus he was called, and found the patient rapidly sinking, apparently from internal hemorrhage. An autopsy was denied.

It seemed probable that the placenta was attached to the left tube or ovary. He inferred that, had it not been for the severe straining after taking a cathartic, the case would have pursued the usual course after death of the fœtus, viz., decomposition, abscess formation, constitutional symptoms, rupture, and discharge through the rectum or vagina. He was unable to state the strength of current used, but according to the patient's statements it was a strong one.

Before the discussion on this paper DR. ROBERT A. MURRAY presented specimens and gave the history of a case of

HÆMATOMA OF BOTH OVARIES

in a patient operated upon on December 2d. She was married at the age of twenty-four, and nine months afterward had a normal delivery. Sixteen months later she had another normal delivery. She ceased nursing the last child at the tenth month, two months before Dr. Murray saw her. The second child had been delivered in February, and in April she felt signs of pregnancy, and five months later thought she felt movements, but her physician said she was not pregnant. In November she menstruated, and this month she consulted Dr. Murray, to learn whether she was pregnant, or what was wrong with the womb. On the right side he found a tumor the size of an orange, continuous with the Fallopian tube, which seemed enlarged. The tube was fixed and immovable. He could determine nothing on the left side except an indistinct hardness. There was a question regarding extra-uterine pregnancy. Dr. Gillette and Dr. Janvrin were consulted, both of whom were convinced of the presence of salpingitis, and of possible extra-uterine pregnancy. At the operation they found an extreme amount of firm adhesions, which rendered the operation most difficult and prolonged it three hours. The ureter on either side was displaced and passed through the mass of exudation, and had to be exposed a distance of eight to ten inches. The bleeding was profuse. No evidence of extra-uterine pregnancy was found. The tumor on either side was a hæmatoma with pyosalpinx.

DR. H. C. COE had been interested in the case of Dr. Tuttle, which resembled in some parts of its history one which he had related at the Obstetrical Society. The fœtus in his case had been encysted in the abdomen an unknown period, and the bones were finally discharged through the vagina. They were the remains of a fœtus of about the fourth or fifth month. The woman had been married nineteen years, and had not missed a period. Before rupture of the sac Dr. Hunter saw the patient in consultation, at which time it seemed a clear case of impacted fibroid uterus. Hemorrhage was such that they had despaired of the patient's life several times. When the sac ruptured, which took place during an attack of peritonitis, and the woman's health permitted, they thoroughly cleansed the cavity, and complete recovery ensued.

The difficulty of diagnosis of extra-uterine pregnancy was daily being made more and more apparent. The case of Dr. Murray was an illustration. He had also seen a case of pyosalpinx with similar displacement of the ureter. There was with it pyonephrosis, and he would suspect renal trouble in Dr. Murray's case.

DR. JEWETT recognized the difficulty of diagnosis in Dr. Tuttle's case, but when it was once made he thought the question of the propriety of laparotomy was immediately raised.

DR. H. T. HANKS remarked that we now saw many more cases of extra-uterine pregnancy than were formerly recognized. A doctor, whose wife he had recently attended for presumable extra-uterine pregnancy, told him that his father, who had a large practice in a country town, had within the past ten years attended three autopsies in which there was ruptured tubal pregnancy. He believed that many cases of sudden collapse in married women, the first or second month after missing a period, were cases of extra-uterine pregnancy. We should do all in our power to make an early diagnosis. Of the cases lately reported in an English journal, 31 were not treated, and 18 of these died. Nine of the 18 fatal cases died before the end of the third month. As soon as the diagnosis had been made the physician ought to resort at once to the best treatment at his command, and not wait for his patient to visit Chicago or New York, for delay meant danger. If the fœtus had not passed the third month there was unquestionable authority in favor of electricity. In such cases as that of Dr. Murray, it was only the most skilled surgeon who could perform the operation and have the patient recover. Kill the fœtus with electricity, and subsequently, if the symptoms called for it, remove the remains; the operation would then prove less difficult than was the primary one.

DR. A. F. CURRIER thought one of the most important questions had been raised by Dr. Hanks, that of electricity *versus* laparotomy. It was evident that electricity could not be regarded as perfectly safe and sure in all cases. Again, the diagnosis of extra-uterine pregnancy might erroneously be made, the current passed, and the fact then be learned that the case was one of pyosalpinx. We might say we had done no harm, but were we sure of it? At any rate, the pyosalpinx remained and no advance had been made. It was claimed by the advocates of electricity that it should be used before the fourth month, but it was also during just that time that laparotomy offered its greatest advantages.

A case then under his observation gave a history much like that of Dr. Tuttle, although the tumor was known not to be adherent to the rectum. At first there was absence of marked colicky pains; hemorrhage had continued several weeks; pieces of membrane had been passed; the breasts gave signs of pregnancy. A month ago, Dr. Janvrin saw the patient with him, and they were in doubt about extra-uterine pregnancy. To-day both thought extra-uterine pregnancy existed, and they proposed soon to operate. Under such circumstances of doubt he thought it was cruel to resort to other treatment when laparotomy would dissipate the clouds. He believed the day was not far distant when the use of electricity in extra-uterine pregnancy would be laid aside. When the diagnosis had been made there should be no more hesitancy in doing laparotomy than in a case of pyosalpinx.

DR. A. P. DUDLEY would have opened the abdomen at once in Dr. Tuttle's case, after learning that he could not remove the after-birth through the rectum. Regarding diagnosis of extra-uterine pregnancy, there were still many things to throw doubt upon it in a given case. Symptoms which resembled it in many cases arose from intestinal adhesions. He had repeatedly found nausea and vomiting, and other reflex symptoms resembling pregnancy, due to pelvic adhesions, and relieved when these were broken up during laparotomy. The pelvic organs dragging upon the adhesions, and through them upon the intestines, had caused the symptoms.

THE CHAIRMAN thought, with reference to the propriety of laparotomy in Dr. Tuttle's case, that if the diagnosis had been made fairly well it would certainly have been advisable to perform laparotomy early, and all agreed that the results of such an operation in the early months should be successful. The case certainly could not be put down as one of successful treatment by electricity.

In Dr. Murray's case, they were pretty firmly convinced before the operation that the condition was one of

pyosalpinx or of hæmatoma, and not of extra-uterine pregnancy. With due deference for Mr. Tait's opinion, he felt convinced, from the reports of his own cases, that in the large majority of them in which he had removed only a small clot, the condition was not one of ruptured tubal pregnancy, but of hæmatocele or hæmatoma. Contrary to the view of Dr. Hanks, he held that the removal of a tubal pregnancy before the third or fourth month was a very simple operation, and statistics were accumulating in proof that the tumor could be much more readily removed before the use of electricity than after. He strongly favored laparotomy *versus* electricity.

DR. TUTTLE closed the discussion, and called attention to the marked collapse of his patient, on slight disturbance of the after-birth, as precluding for the time laparotomy or other operation.

DR. H. C. COE then read a brief paper (see page 63), entitled

THE IMMEDIATE APPLICATION OF FORCEPS TO THE AFTER-COMING HEAD IN CASES OF VERSION WITH PARTIAL DILATATION OF THE CERVIX.

DR. W. R. GILLETTE said that he had always found, when the cervix dilated sufficiently to allow the shoulders to pass, that there was also room enough for the passage of the head when pressure was made upon this from above and without; consequently he had never had occasion to apply the forceps to the after-coming head. He was unable to recall his statistics of mortality to the child.

DR. COOPER had frequently met with the class of cases described by Dr. Coe, in which there was great danger to the child from only partial dilatation of the cervix after version. The difficulty at the cervix would be overcome after a time, say ten to twenty minutes, so that the head could pass, but very often it was five or six minutes too late. A certain amount of time, however, could safely be allowed after version for dilatation and passage of the head, and he believed the child was often sacrificed because of undue haste in extraction.

DR. MALCOLM MCLEAN would, if necessary, stand alone the champion of the old method of bringing the chin down in the line of the superior strait, and allowing the further expulsion of the head to be brought about by pressure from above. He did not believe there should be any traction on the body whatever. He had always followed this practice, and had not seen a case, until lately, in which it seemed desirable to apply forceps to the after-coming head. He could give the statistics of his last thirty-two cases in which the head was delivered last, and in none had he lost the child. He believed death to the child was commonly due to traction upon the body and injury to the cord or internal organs, and not to pressure on the funis.

DR. COOPER expressed disagreement from the last remark of Dr. McLean. He never knew death to result from injury. When it took place, suffocation was the cause.

DR. R. A. MURRAY thought there were some cases in which the use of the forceps to the after-coming head was called for, although few; in ordinary presentations, the forceps were sometimes applied because they acted auxiliary to dilatation, which might be slow, and he thought they might have a similar effect in the cases under consideration. In some cases of fleshy women, aid from pressure on the head from above could not be obtained, and there especially the forceps might be useful.

DR. JEWETT had long been an advocate of the forceps applied to the after-coming head in cases of only partially dilated cervix, and in which the child's shoulders were narrow compared with the head. He had not found their application difficult, although the next speaker, Dr. Coudert, had had a different experience.

DR. COE closed the discussion, calling attention to the fact that the paper referred to only a small class of cases in which it was necessary to make use of the forceps; while in the majority, urgent measures were not called for, and the child could be saved by expression, and by manipulation through the vagina.

SECTION IN SURGERY.

Stated Meeting, December 10, 1888.

R. F. WEIR, M.D., CHAIRMAN.

DR. W. T. BULL presented (see page 62)

A CASE OF PRIMARY TUBERCULOSIS OF THE TONGUE.

FISTULA IN ANO; RESTORATION OF THE SPHINCTER.

DR. L. BOLTON BANGS presented a man upon whom, some eighteen months ago, a surgeon had performed the usual operation for fistula in ano, and divided the sphincter. The result did not prove successful, and, after having passed from one institution to another until he had made nearly the full round of all in the city, he fell into the hands of Dr. Bangs. There was absolute incontinence of fæces and gases, and he had been obliged to give up all work. A funnel-shaped cavity occupied the place of the normal anus, large enough to receive three fingers. He had been told that nothing could be done for him, but Dr. Bangs concluded to try a simple operation, consisting in dissecting out the broad leathery cicatrix of triangular shape until cellular tissue and the mucous membrane of the rectum had been reached. The sphincter had retracted to the opposite or left side. In order to hold the edges of the wound firmly together, and prevent retraction, it was necessary to pass three silver-wire sutures, after which six deep silk sutures were introduced. The edges of the mucous membrane and also of the skin were then stitched with catgut. The patient now had complete control of fæces and gas.

THE CHAIRMAN remarked that such cases float occasionally into the hands of surgeons of all hospitals, and he had seen his share. Several times he had attempted to close the cavity and restore the anus, but he had to confess to failure except in one instance, in which he made a free dissection, taking out quite a bridge of tissue. He thought his error, and probably that of others, had usually been due to overlooking the fact that the circular muscle of the anus when divided made very extensive retraction.

DR. CHARLES A. POWERS presented a case of

PRIMARY UNION OF COMPOUND FRACTURE OF OS CALCIS.

DR. ROBERT ABBE, who completed the treatment of Dr. Powers' case by making a flap to heal the wound, said the patient came to him about three months ago, having upon the deficient heel of the right foot a large, thin cicatrix adherent to the bone and attempting to repair its centre by very poor granulations. This had been going on many months without any progress, and it was evident the cicatrizing process had about ceased. The ulcer was nearly two inches by an inch and a half. He believed that in times past such a foot would have been amputated because of its uselessness with the heel in that condition. The preparatory treatment consisted in keeping the sore in a stimulated condition, and in placing the left knee in plaster of Paris, bent at a right angle, for a week before the operation, to accustom it to the position. Then a large flap was dissected up from the calf of the unaffected limb, the base directed upward, and larger than the surface to be covered in order to allow for shrinkage. Then the heel was prepared by cutting out the cicatrix and ulcer until healthy tissue was reached. The flap, after it was stitched into the large opening, had its base directed downward, with the leg crossing the affected member in the form of a figure 4, in which position it was maintained two weeks by plaster of Paris. The patient felt no inconvenience during the union of the flap, which proved to be primary throughout, and only required at the final dressing separation at its base under cocaine anæsthesia.

DR. W. T. BULL, being asked his experience with large

flap-transplantations, first remarked that in the case just recited the results justified the highest commendation, and he would add that the primary union of bone in an open and severely contused heel was a most satisfactory tribute to the care and aseptic management of the case by the surgeon in charge. He had had occasion to see the patient several times while in the care of Dr. Powers, and, never having seen the os calcis unite in a compound fracture, he did not expect it in this case; yet in so large a wound no pus formed during the three weeks it was healing. He had had no experience with transplantation of skin-flaps to the heel, but considerable in relation to the forearm, hand, and fingers. He believed the treatment should be resorted to more frequently than it had been and as soon as the surgeon had become convinced that the wound would not heal. Two conditions were necessary for success: (1) The operation should be undertaken before the patient was reduced in general health or had lost local vitality; (2) arrangement must be made to secure absolute immobility during union. Then one was often tempted to make the flap too small at the base, through fear of leaving too great an open space behind. This wound, however, could be healed by ordinary dressings.

THE CHAIRMAN thought the course adopted in this case, of accustoming the limb to its strained position before the operation, was a good one, especially in operations on the lower extremity.

DR. SYMS mentioned a case showing what sad results might possibly have been prevented by flap-transplantation as in Dr. Powers' case. When he was interne in Bellevue Hospital a tenotomy was performed on a man for talipes equinus. A very persistent ulcer developed which kept the patient abed for months, and he finally passed into acute dementia, was sent to the asylum, and a year or two afterward was brought back to the hospital and his foot was amputated.

DR. ABBE said, regarding the patient being able to bear a strained position, that a severe test occurred in the case of a woman who had a cicatrix involving the entire palm of the hand. He dissected it out and covered the wound by clean skin dissected up from near Scarpa's space, the hand being shoved under the skin, which was left attached at either end. The thigh had to be put up in plaster of Paris. The result was good, but it required morphine constantly for two weeks to enable the patient to bear the pain.

DR. ABBE presented a lad with an

EXTENSIVE NÆVUS,

reaching from the tip of the thumb, along the side of the forearm and arm, up over the shoulder, and terminating on the neck. It was also present in a slighter degree over the trapezius muscle. Two years ago, when treatment was begun, it formed cavernous masses of nævous tissue in the subcutaneous and cutaneous tissue along the arm and on the shoulder. It was, indeed, the most extensive case which the doctor had seen, and seemed to be beyond surgical control. By piecemeal, however, it had gradually yielded to treatment, and was perhaps two-thirds cured. It had extended somewhat since treatment was instituted.

The treatment had been by various methods. First he tried electrolysis, introducing into the tissue a number of fine needles, as is done for the destruction of abnormal growth of hair. This procedure did well on the hand, but it was not applicable to the arm where the cavernous masses were much larger, and here he used the actual cautery, puncture with the hot iron and the paquelin cautery. At the flexure of the elbow was a mass two-thirds the size of one's fist, which he excised. It had left a small ulcer, which had not yet healed. On the upper part of the arm he had employed still another method, which offered better results than any of the others. It consisted in transfixing the affected veins with a platinum wire, passed by attaching it to silk threaded on a needle. The platinum loop, which included the venous mass, was brought to the proper heat by the electric current to make section. The extensive mass on the shoulder, which had disappeared under this treatment, would probably have led to the patient's death, through hemorrhage, had excision been resorted to. At the last operations with the galvano-cautery Professor Esmarch was present, and said that in similar extensive conditions he had transfixed the mass with a thread which had been soaked in a solution of persulphate of iron and permitted to dry. When the needle was first passed there was hemorrhage, but it immediately ceased when the styptic came in contact with the tissues. No harm had come from the treatment, he said, while the mass usually shrank.

THE CHAIRMAN remarked that the speaker had in this case made use of various methods of treatment, all of which were eminently practical. For small nævi he thought there was nothing better than the electrolytic needle. That day he had seen a child again which had been treated by this method, with satisfactory results, for a large subcutaneous nævus involving the tissues about the eye and face. He confessed to considerable hesitation in the use of persulphate of iron, for he had seen severe cardiac and cerebral symptoms follow the injection of a few drops of the solution into a nævus on the face.

DR. W. T. BULL had never seen a nævus so extensive as in this case, but the result of the treatment here would be a great encouragement in similar conditions. He had had experience with excision in only one instance, that of a nævus covering the entire posterior surface of the elbow. He was astonished at the amount of hemorrhage which followed, placing the patient's life in jeopardy, from which he was rescued only by the timely venous infusion of a salt solution. He would not undertake excision again unless the venous enlargement were of small area. Puncture with thermo-cautery or galvanic loop would seem preferable, while for small nævi he would use needles and electrolysis.

DR. J. D. BRYANT said, regarding excision, that he once employed this method on a nævus involving nearly the entire lower lip. He made compression of the vessels at the angle of the mouth, as was done before operation for epithelioma of the lower lip, but after removing the nævous tissue there was profuse hemorrhage, which necessitated the use of the whip-stitch with catgut. Good union resulted.

DR. ABBE added that in his case the veins were not alone involved, but the cutaneous arteries as well, and most of the hemorrhage during the operation had been arterial.

DR. J. D. BRYANT then related the history of a case (see page 40) of

LAPAROTOMY AND NEPHRORRHAPHY.

THE CHAIRMAN referred to the importance, in anchoring the kidney, of passing the suture low down on the organ, and of including some of the fibrous capsule to prevent tearing out.

DR. MORRIS suggested that Dr. Bryant would have had less difficulty in reaching and maintaining the kidney in position had he rolled the patient over on the pillow, allowing the organ to gravitate to the wound.

Regarding

MECHANICAL TREATMENT

for movable kidney, the Chairman and Dr. Bryant had had little success.

DR. W. B. DE GARMO had found a fair percentage of cases of floating kidney relieved by mechanical means. He had had three cases, previously operated upon without success, which he had relieved by a form of truss with a strong spring carried around from the opposite side of the body. He thought, however, that any operation which was safe and offered a permanent cure should be preferred. The pad which he had employed was as large as one's hand, and was placed lower down than theoretically one might suppose was indicated.

DR. MORRIS instructed his patients to apply the bandage and pad as by trial they found it gave most comfort.

DUPUYTREN'S FINGER-CONTRACTION.

DR. WILLY MYER presented a man, sixty years of age, a druggist by trade, with contraction of the palmar aponeuroses, causing flexure of the fingers on both hands. The man's history and occupation did not permit of a mechanical cause in explanation of the case. In truth, we did not yet know what was the cause of the trouble in patients not obliged to work with the chisel or similar object. The treatment which had been practised in this affection had varied, and consisted in dividing the tissues presumably involved. The speaker had done Kocher's operation in the present case. He put an Esmarch bandage on the limb, made a longitudinal incision, readily pared the skin from the thickened aponeurosis, and, while it was held back with retractors, removed the aponeurosis from the deeper parts, and was then immediately able to straighten the fingers. He then applied catgut sutures, a piece of rubber gauze, and bandaged antiseptically. The first two days the patient had a good deal of pain but no fever. The fingers, formerly bent to an angle of forty-five degrees, could now be straightened. The other hand would be operated upon later.

THE CHAIRMAN said that three years ago, without knowledge of what Kocher had done, he had employed the same method in one case with a very good result.

DR. ABBE was glad to see the general profession becoming cognizant of the fact that this small but very important deformity could be relieved by a simple operation. However, there were yet scattered throughout the country many cases which in their locality were believed to be incurable. He had come to regard one method as better than any other, viz., multiple cross-sections. It only required the use of cocaine. The hand, after dividing the bands, should not be placed in extension; the fingers should rest comfortably open. When extension was adopted the patient was likely to suffer neurosis. The injury from overextension was also dwelt upon by the Chairman.

DR. POWERS said that since Dr. Abbe read his paper on Dupuytren's contraction, a year ago, he had operated in four cases, in each of which the contraction was overcome and the pain which the patients had previously suffered was relieved. The cases treated without the dorsal splint had done better than those treated with it.

DR. A. M. PHELPS did not believe it possible to cure Dupuytren's contraction with splints; under such treatment it would become aggravated. In a mild case like the one exhibited by Dr. Myer he would employ subcutaneous puncture as done by Adams, but where the finger was drawn to more than a right angle he would do Kocher's operation. The hand should not be put in extension. By overextension he had ruined one case. He was fully prepared to indorse the neurotic origin of the disease. He did not believe it was due to the gouty diathesis. When the contracting band was relieved the neurotic condition disappeared.

A SIMPLE METHOD OF FORCIBLE FEEDING.—Dr. I. S. Ivanoff, of Kostroma, recommends the following method for forcible feeding, which he has successfully employed in the case of an insane lady who absolutely refused to take food, in consequence of her having some fixed idea on that point. Having seated and steadied the patient, he firmly closes her nostrils by pressure, which causes her to open the mouth for breathing; then he slightly bends the lady's head backward and pours some liquid food into her mouth, by means of an ordinary spoon; she appears to swallow without much struggle The method is said to be very simple, and by far less troublesome and more convenient than the ordinary introduction of a gastric sound through the nose.—*The St. Louis Medical and Surgical Journal.*

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE AT THE PATHOLOGICAL SOCIETY ON THE MORBID ANATOMY AND PATHOLOGY OF CHRONIC ALCOHOLISM—THE DEBATE CONTINUED BY DRS. DICKINSON, BUZZARD, FINLAY, PITT, SAVAGE, AND SHARKEY—WHAT IS AQUA MENTHÆ?—AN ATTACK ON HOSPITAL EXTRAVAGANCE—AID TO THE PASTEUR INSTITUTE.

LONDON, December 24, 1888.

THE debate on the morbid anatomy and pathology of chronic alcoholism was resumed at the Pathological Society on Tuesday evening last. Dr. Dickinson showed a drawing of a liver with enormous increase of connective tissue, and he maintained that the overgrowth of fibrous tissue was the essential part of cirrhosis of the liver and of granular degeneration of the kidney. He had often seen what appeared to him to be irresistible evidence of this new-growth in the cirrhotic liver and granular kidney of childhood, where the new-growth was very profuse and highly nucleated. He had satisfied himself that new vessels were developed in this new tissue. Whatever might be the minute anatomy of cirrhosis of the liver, there could be no doubt as to the effect of alcohol in causing it. Dr. Dickinson then adverted to the evidence as to the special liability to hepatic disease of persons whose occupations brought them in special contact with drink. There was no such evidence with regard to kidney disease; the total of renal disease was not greater in the drink class than in the others. The effect of alcohol on the kidney had been overrated. The fact appeared to be that the liver was acted on chiefly by alcohol, the kidney by a variety of causes. As to tubercle, observations showed a greater frequency of it in every organ in persons trading in drink, as compared with others. No doubt could be entertained that drink promoted tubercle instead of preventing it. In conclusion, Dr. Dickinson asked whether, though alcohol undoubtedly caused many diseases, there were none, or no morbid conditions, which it tended to prevent. He observed that the facts indicated that endocarditis was less frequent in the drink traders than in others.

Dr. Buzzard said he would not discuss the clinical aspects of alcoholic neuritis, which were now generally recognized, except to draw attention to the fact that, alongside of the complete immunity of the functions of the bladder and rectum usually observed in these cases, there was in females an almost constant suppression of the catamenia during the many months of illness usually involved. He had not seen any reference to this circumstance. Agreeing with Dr. Payne, that the acceleration of the heart's action was probably due to lesion of the vagus, he suggested the pneumonia which occasionally terminated cases of this kind might be due to a similar cause.

Dr. Payne had referred to the two kinds of microscopical changes found in the peripheral nerves, and had remarked that, though very generally the changes were found together, sometimes the signs of parenchymatous degeneration, at others those of interstitial inflammation, predominated. Dr. Payne had gone on to say that he believed both to be produced by the direct action of alcohol.

Dr. Buzzard said he could not acquiesce in this view. He had long felt that, notwithstanding the absence of observable lesion, there was probably some change in the cord which brought about the coincident and limited affection of so many nerves, and he referred to the suggestion he had made in his Harveian Lectures, in 1885, viz., that it was upon vaso-motor centres in the bulb and cord that the toxic action of alcohol was primarily excited.

Dr. Finlay said the appearances presented by the mi-

croscopical specimens which he was showing bore out in detail much of what had been said by Dr. Payne, as to the changes found in certain parts of the nervous system in alcoholic paralysis. Sections of the cord were shown, and they were healthy, though he did not deny that degenerations might occur. The morbid changes found in the nerves were as advanced in cases in which the cord appeared to be perfectly healthy as in cases in which changes in the cord had been observed. One of the most interesting points in connection with alcoholic paralysis was its association with tubercular disease. He thought there was a causal connection, and believed that excess in alcoholic indulgence led to both. It was quite true that persons suffering from phthisis, or having a tendency to it, might be benefited by a certain amount of alcohol, but this was a very different thing from the bacchanalian bouts of drinking indulged in by the patients whose organs were now being discussed.

Dr. Pitt brought forward some statistics based on the post-mortem records of Guy's Hospital, extending over the last twenty years. An interesting point to which Dr. Pitt drew attention was, that in as many as 22.5 per cent. of those dying with cirrhosis of the liver acute tuberculosis had been found post mortem, and the younger the patient the more liable he appeared to be to tubercle as well. With reference to diseases of other organs than the liver and kidney, which seemed to have some relation to alcohol, there had been three cases of acute cerebral meningitis, one of suppurating meningitis, and one of pachymeningitis.

Dr. Savage discussed the relation of alcohol to nervous and mental diseases, and gave some of the results of his extensive experience as resident physician to Bethlehem Hospital for the Insane. During the last seventeen years, he said, out of 4,000 patients admitted into Bethlehem only 133 had drink given as the cause of their insanity. This was a very small proportion, and was not to be considered as representing the proportion of insanity produced by excess of stimulants; but in Bethlehem, where the patients were specially selected, many drunkards were excluded. Of these, 133, less than one-fifth, had any insane relations, so that the persons so affected did not come from the nervously unstable. Thus, drink produced insanity in many who were otherwise fairly stable. On the other hand, drink could be shown to be the starting-point of neuroses, both in the individual and in the family. Only a very small proportion of those becoming insane as the result of alcohol were suffering from general paralysis. Many authors considered alcoholic excess to be the chief cause of general paralysis; Dr. Mickle believed it to be the great exciting cause. Dr. Savage said that he would say that, though alcoholic excess was common in general paralysis, and might be in some cases the predisposing, in others and larger numbers the exciting, cause of the mental symptoms first noticed in general paralysis, yet he had not found more than seven per cent. of the cases to depend on alcohol alone as a cause.

Dr. Sharkey discussed the action of alcohol upon the liver, and showed two microscopic sections in illustration of the view he put forward, viz., that the poison acted first on the portal vein and the connective tissue surrounding it, and that the liver-cells in its immediate neighborhood might remain healthy for a long time. In other organs, the spinal cord for instance, he had seen the vascular and parenchymatous changes side by side. It was probable that individuals might differ in this respect. Observers differed as to the effects of alcohol on the kidney; his experience in the post-mortem room had left him strongly imbued with the opinion that it was a potent factor in the production of chronic renal disease, though its injurious effects were far more frequently exemplified in cirrhosis of the liver. With regard to the nervous system, it seemed probable that the action of alcohol fell most intensely upon peripheral nerves and muscles, and much less upon the central nervous system. So widespread might be the effects of alcohol on nerves, that it was a question whether any nerve was beyond its reach; and Dr. Sharkey referred to a case he had published, in which, in addition to the nerves and muscles of the limbs, the phrenic and pneumogastric nerves, together with the muscles they supplied, were affected. But it was probable that even nerves of special sense might not escape. Some authorities supposed that certain cases of tobacco amblyopia, so called, were really cases of alcoholic amblyopia, though he was not aware that any indubitable case of this axial change of the optic nerve in alcoholism had been published. Dr. Sharkey then referred to a case which came under his care, of what he believed to be alcoholic retinitis. Referring to Dr. Mott's case of fatty degeneration of the heart and sudden death in a drunkard, he suggested that the cardiac degeneration might be the result of alcoholic neuritis, just as the muscles of the limbs degenerated as a consequence of disease of their nerves. Phthisis, he said, was frequent in cases of alcoholic poisoning, and, as Dr. Payne had said, was almost the rule in alcoholic paralysis.

What is Aqua Menthæ, or rather, what is the dispenser to understand by it? This is a question which has recently excited the pharmaceutical world, and the *Chemist and Druggist* has sent out a number of post-cards to members of the profession to elicit their opinion. Most of the replies state emphatically that the expression Aqua Menthæ is one which ought not to be employed, but the majority of prescribers seem to think that when it is used Aqua Menthæ Piperitæ is intended. Pharmacists, however, especially in certain districts, appeal to old formulæ, and assert that spearmint is intended; and it is reported that the examiners at the Pharmaceutical Society expect this answer from candidates. On the other hand, there are other districts, including the whole of Scotland, where spearmint is hardly ever prescribed at all.

Mr. Michelli, Secretary to the Seamen's Hospital, and late Secretary to St. Mary's Hospital, has recently read a paper before the Hospitals Association, which has caused great indignation in certain quarters. Mr. Michelli's paper was entitled "Hospital Extravagance and Expenditure," and he commented vigorously on the different ways in which money was wasted in hospital administration. Small and special hospitals were censured most severely for extravagance; their administration, he said, cost from fifty to seventy-five per cent. more per bed than that of the large hospitals.

A question was asked in Parliament last week, whether the Government would consider the propriety of affording pecuniary assistance to the Pasteur Institute, as English patients had been treated there free of charge. The Chancellor of the Exchequer said it would be necessary to inquire into the circumstances of these patients, as, if many of them were persons of means, it would clearly be for them to contribute to the funds of the Institute.

THE PHYSICAL PERFECTION OF MAN.

To the Editor of The Medical Record.

SIR: Dr. Mettler, in The Medical Record of December 8, 1888, paints his views on "The Nature of the Physical Perfection of Man" with optimistic colors, if not with scriptural precision. He admits the spiritual perfection of the first man, but denies him absolute physical perfection, accepting the statements of paleontology and materialistic evolution as antagonizing a belief in his dual perfection. Truly a theory nearly as old as the hills, if paleontological, if not in accord with more modern orthodox theology. The perfect spiritual nature is the condition requisite to the progressive development of the organism as a whole, and hence the spiritual is constantly exerting a perfecting influence upon the physical, in accord with its own perfect nature. The absolutely perfect man is thus a necessary result in the dim and distant future. Of course this hopeful, scientific (?)

view has an elaborate logical foundation upon which it rests. Let us examine it. There are two forms of perfection, the mathematical and the utilitarian. The first includes bilateral symmetry and symmetry of the homologous series, and this tendency is manifest in all animal life, and perfection is only delayed by the disturbing ele ments of man's environment, heredity included. The problem then stands: Only allow man to so understand these perturbating forces found in one's environment so that he may neutralize them, and the "anima," or spiritual nature of man, or creative force, the author using them indiscriminately, will then have unrestrained influence upon the physical form, producing an archetypal, ideal man, bilaterally and symmetrically developed in the minutest particular. And lo, and behold! the perfect man is evolved. Would that we might photograph him. Phidias, in his most exalted moments, never dreamed of such perfection of the human form. Note how his hair is disposed with wondrous symmetry on either side of a central part. His nose shows nothing of the ill-defined and warty character of its ancient prototype. Perchance that evil gastronomic appendage which in fœtal life violated the bilateral law and turned from the median way, will then, having more perfect knowledge, flop back into its ancient and honorable symmetrical position, and the whole train of sinful organs, consciously or unconsciously, who have followed this seat of indigestion and have caused no end of study and perplexity to the student of bygone ages to explain the intricacies of the homologous series, will, with becoming humility, under the inspiring influence of the "anima" march back to their pristine bilateral symmetrical locations. All hail that glorious day when the prodigals return and man shall be perfect. Then shall he be so evenly balanced that no temptation shall allure him, and heaven shall court his entrance. Search the "Arabian Nights" and can we find a more enchanting and delusive dream.

We do not deny the existence of bilateral symmetry, but that it is the chief element to be desired in the perfect man we do regard as visionary and without the scientific basis that our author claims. The tendency of modern scientific thought is to emphasize environment, and this bilateral method is largely influenced by uniform blood-supply, uniform exercise, identical surroundings and mode of development. Undoubtedly, too, it is obedient to vital laws, the nature of which have thus far been uninterpreted. But that this body of ours will attain a higher state of perfection in the future than it has in the past, we, too, hold is an untenable theory without sufficient foundation in facts. Has all vegetation, too, been swayed by this bilateral law, and are all the trees of to-day more symmetrical than those of five thousand years ago? Shall we in that later time have the same number of branches, leaves, and twigs balancing upon a central body? If so, I am glad I do not live in that period of perfect development, for to me the infinite variety of beauty in nature's storehouse is most desirable. Perhaps this spiritual perfection will at length close all inanimate nature within her grasp; then the mighty mountains' grandeur will depart as their ruggedness is planed off and the symmetrical cone and pyramid alone remain.

For me, I prefer to accept the old-fashioned scriptural statement, "So God created man in his own image." And as God is the embodiment of absolute perfection, the first man inherited a perfect physical body as well as spiritual nature, notwithstanding some so-called scientists read the teachings of paleontology otherwise.

This perfection remained so long as man harmonized with his environment. After his disobedience and fall this adjustment was only partial; friction and disease resulted, and only as man's knowledge of hygienic laws becomes more comprehensive, and his obedience to them becomes more implicit, can we hope for a better adjustment to his environment and the perfect physical man, now lost, regained.

As physicians, we congratulate ourselves that the average length of life is increasing, being due, as we believe, to the principles enunciated.

To be sure, man is essentially double, and for a very wise reason, if one organ is injured the other remains; but this double nature does not predicate absolute or potential perfection. We regard the utilitarian theory of perfection with most favor—his accurate adaptation for the purpose of his creation.

A. C. HAVEN, M.D.

LAKE FOREST, ILL.

THE RIGHT OF IT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The charge made by the *Cleveland Medical Gazette* against the medical profession of this city, to which you have given a wide currency by your comments in THE MEDICAL RECORD, is not borne out by the facts. There are a number of hardworking physicians in Cleveland who have contributed, and are contributing, original work in dermatology, gynecology, surgery, obstetrics, physiology, histology, school hygiene, etc.—work which such journals as THE MEDICAL RECORD, *The Boston Medical and Surgical Journal*, *The Journal of Cutaneous and Venereal Diseases*, and the like, have deemed worthy of publication, and which, moreover, has been given a still wider publicity by being copied in British and Continental journals.

It is, doubtless, a little rough on the editor of the *Cleveland Medical Gazette* that Cleveland physicians should seek the wider circle of readers afforded by the metropolitan journals when they have anything original to contribute to the literature of their respective specialties; but for him to retort that such work is not being done, and for a leading journal like THE MEDICAL RECORD to assume that the retort is a statement of fact, does a gross injustice to a group of workers to whose credit, rather than to whose blame, be it said, that they are but little given to wearying their professional brethren with prolix rehashes of other men's work. Very respectfully,

L. B. TUCKERMAN, M.D.

CLEVELAND, O., December 16, 1888.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 6, 1889, to January 12, 1889.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon. By direction of the President, will report in person to Brigadier-General Wesley Merritt, President of the Army Retiring Board at Fort Leavenworth, Kan., for examination by the Board. Par. 1, S. O. 4, A. G. O., Washington, D. C., January 5, 1889.

JOHNSON, R. W., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from duty at the United States Military Academy, West Point, N. Y., and will report to commanding officer at San Carlos, Ariz., for duty at that post. Par. 10, S. O. 7, A. G. O., Washington, D. C., January 9, 1889.

JOHNSON, RICHARD W., Captain and Assistant Surgeon. Leave of absence granted for fourteen days. Par. 1, S. O. 8, A. G. O., Washington, D. C., January 10, 1889

PILCHER, JAMES E., Captain and Assistant Surgeon. By direction of the Secretary of War, will repair from Fort Wood, N. Y. Harbor, to Philadelphia, Pa., at such time as his services can be spared, for the purpose of giving instruction to the Hospital Corps of the First Brigade National Guard of Pennsylvania. Par. 6, S. O. 8, A. G. O., Washington, D. C., January 10, 1889.

ON SPASMODIC URETHRAL STRICTURE FROM ANAL FISSURE.[1]

BY L. BOLTON BANGS, M.D.,

SURGEON TO ST. LUKE'S AND CHARITY HOSPITALS, NEW YORK.

THE brief clinical record which I shall present to you this evening contains no novelty, and is entirely within the line of your experience, but it seems to me worthy of your consideration, not only because it may give an opportunity for discussing an interesting subject, but also for the purpose of giving me the advantage of your criticism upon the correctness of my observations.

It is probably within the memory of many of those present that some years ago an argument was made against a Fellow of this Academy who had then, and has since, written largely upon spasmodic stricture of the urethra, and who denominated such conditions by the title of "urethrismus;" and although there may yet be some surgeons who deny the existence of permanent spasmodic contracture of the muscles of the urethra, forming an obstacle to the exit of fluids and the introduction of instruments, still I think that a large number of observers have confirmed the statements of Dr. Otis. The case here recorded seems to me to be, without doubt, one of more or less permanent stricture of the urethra, due to reflex action of the spinal cord from an irritation at the anus.

The subject of this report was aged forty-one, a painter by trade. Twenty years ago he had syphilis, followed by secondary symptoms, but for many years he has had no evidence of it whatever. For several years he has been subject to attacks of painter's colic, and at such times the associated constipation has been very obstinate. About six years (he thinks) ago he began to have indescribable sensations in the region of his bladder, and pain during urination, but he had never had any urethritis or disease of the urethra or bladder to which these sensations could be attributed. About two years ago he acquired a specific urethritis which lasted acutely some weeks; then became chronic, and finally terminated at the end of six months. Six months later, that is to say, about eighteen months ago, he had an attack of painter's colic, accompanied by constipation, and then experienced intense pain in the rectum, which was most marked after defecation. This pain became constant, gradually increased to extreme intensity, and he suffered from it, both after and before a stool, or, as he expressed it, "whenever it begins to fill up down there."

With this pain in the rectum, he had a gradually increasing difficulty of urination, the urine passing in a small stream, and at times only in drops, accompanied with pain in the penis and in the pelvis generally.

At length the difficulty of expelling the urine became such that his physician was compelled to resort to the use of the catheter, in order to relieve the bladder of a certain amount of urine which was retained. For the two months preceding his coming under my observation his troubles, both as regards the pain in the rectum and the dysuria, increased so greatly that the use of the catheter was continuous, and the latter finally set up a mild form of urethritis, which aggravated his symptoms. The pain referred to the rectum and to the bladder became so severe that he was obliged to resort to hypodermic injections of morphia. When I first saw him, the man's condition was pitiable. He was anæmic, weak, and in constant pain, unable to empty his bladder without the use of the catheter, and under the necessity of being constantly under the influence of morphia. He was unable to discriminate between the pain in his bladder and that in his rectum. He was tormented with frequent desire to urinate, and although he could expel some urine with great straining, the feeling that his bladder was not emptied was so intense that I could hardly restrain him from passing his catheter, which he always carried in his pocket for the purpose. I sent him into St. Luke's Hospital, and on the next day examined him. His meatus urinarius admitted 32 French bougie à boule. At four and three-fourths inches was a stricture of 26 French. A solid sound of the latter size (26 French), after being obstructed for a few seconds at the membranous urethra, slipped into the bladder. On withdrawing, it was strongly held by the urethra, which alternately relaxed and contracted upon the instrument until the latter was free in the penile portion. Up to this time it had seemed to me that his urethral difficulty was the principal one, and possibly the cause of his rectal pain. But here was evidently a spasmodic condition of which there could be no doubt, and I questioned what was the cause of it. It is true that such a condition in the deep urethra might be due to a stricture of large calibre in the penile portion, and if it had been nearer to the meatus I should have paid more attention to it; but inasmuch as the patient complained so greatly of the pain in the rectum, I thought that perhaps the secret of the trouble might be found in or about the latter. On exposing the anus it was found to be violently contracted. The anal region was very sensitive and it was only with great difficulty that he could be induced to relax the sphincters sufficiently to enable me to find that he had three bluish-red exceedingly painful fissures of the anus. This seemed a good opportunity to test the question of cause and effect by observing the result of treating the anus alone. Accordingly he was etherized, and the sphincter-muscles were paralyzed digitally until the whole anus was pulpy. Nothing whatever was done to the urethra, and his catheter was taken away. This was on June 7th. On the 9th it was recorded, "The patient passed urine and fæces spontaneously, and with much less pain, being but slight during urination and not nearly as great after defecation."

From this time on his improvement was progressive. There was none of the spasmodic straining to empty the bladder, there was no retention of urine, and the urethritis gradually subsided. Ten days later, a sound as large as could be insinuated through the stricture at 4¾ inches, namely, 30 French, was easily passed into the bladder, without any resistance and without any spasmodic contraction about the instrument upon its withdrawal.

On June 26th he was discharged from the hospital cured. For the past six months he has been intermittently under my observation. He has been treated for the "painter's colic," and has had none of the obstinate constipation, no pain in his rectum, and no trouble whatever with his urethra or bladder. A brief analysis of this case will make clear the points to which I wish to call your attention.

He seems to have had some mild symptoms referable

[1] Read before the New York Academy of Medicine, Section in Surgery, January 14, 1889.

to the urinary apparatus six years ago, but whether these were due to any rectal disease at that time, I am unable to say. He might have had slight disease which healed spontaneously. At all events, there was an interval of comparative freedom from suffering, up to the severe attack mentioned in the history, and soon after he had urethral and bladder symptoms added to those of his rectum.

It is plain that the constipation, associated with his lead-poisoning, was the exciting cause of the fissures, to which may be reasonably attributed the pain in the rectum.

As these progressed, his sufferings continued to increase in intensity, and the symptoms became so commingled that it was impossible for him to discriminate between those of difficult urination and those from the fissures of the anus. Without doubt the attack of urethritis from which he had just recovered greatly increased the sensibility of the urethra, and the response to the reflex action became of a higher grade and rendered the contracture of the muscles more persistent.

It will be observed that the stricture of large calibre in the urethra received no treatment, and, therefore, it seems to me that the conclusion is inevitable that the permanent contraction of the muscles of the deep urethra in this case was due to a reflex from the spinal cord, set up by an intense irritation of the sphincter ani, as evidenced by the entire relief afforded by the treatment of the latter.

127 East Thirty-fourth Street.

CHONDROMA.

By HENEAGE GIBBES, M.D.,

Professor of Pathology, University of Michigan.

I have lately examined two cartilaginous tumors which present features of interest. The first was removed from the mammary gland of a bitch. This tumor to the naked eye showed a nodular, lobulated appearance, and was of considerable size. Sections taken from various parts showed the same structure. The growth consisted of masses of cartilage, spindle-celled sarcoma, and the remains of the original gland. At first sight this would appear to be an ordinary chondrifying sarcoma, but this was not the case. The islands of cartilage were distinctly separated from the sarcomatous tissue, and, although existing side by side, appeared to have no connection one with the other. The masses of cartilage were hyaline, and in the centre resembled normal adult hyaline cartilage, except that the lacunæ were more irregularly placed and rather less in number. The central portion of each cartilaginous mass took the usual deep stain with logwood, in the same manner as ordinary adult hyaline cartilage, while the periphery stained more faintly. The peripheral portion of the cartilage showed a marked fibrillation of the matrix, more pronounced at the edge, and the cells were very irregular in shape. Some of them showed traces of a capsule, while others had none. Many were much branched, and no lacunar space could be seen. The cartilaginous masses in fact represented the appearances seen in a growing normal permanent cartilage, having, however, the lacunæ and cells rather more irregularly placed. The development of this hyaline cartilage could be distinctly traced in numerous instances from the fibrous connective tissue on the outside of and between the masses of cartilage. This fibrous tissue was in an active state of growth and crowded with young connective-tissue corpuscles. So far, there was nothing beyond the formation of a pure chondroma from the mesoblastic elements of the gland. But lying among these cartilaginous masses were tracts of spindle and branched cells which were evidently of a sarcomatous nature. They appeared to be entirely distinct from the fibrous tissue which was developing into cartilage, although lying in close contiguity to it, and their reaction to staining agents was also markedly different. In these cells another process was going on; that is, the formation of bone, if it can be called bone where no lime-salts are deposited by the bone-forming cells. The appearances presented were exactly similar to those of cells laying down bone in the ordinary manner, only they deposited some material which appeared to be entirely organic and certainly contained no lime-salts.

The material formed by the cells had an entirely different chemical reaction to that of the cells themselves. It appeared to be distinctly acid, and this may account for the salts not being deposited. Each cell seemed to be acting the part of an independent osteoblast, and as the material formed by each cell increased, it coalesced with adjoining masses until irregular trabeculæ were formed, resembling in appearance those formed in normal developments of bone in membrane. The cells remained plainly visible, and in many cases retained their processes. What remained of the original gland-structure had undergone pigmentation, showing as masses of cells of a bright-brown color; and some acini still remained, which were plugged with homogeneous casts of the same color.

Throughout the whole tumor indiscriminate calcification had taken place. Some of the hyaline cartilage was calcified in irregular patches, as also some of the material formed by the sarcoma-cells, and in some dense fibrous tissue the same thing had occurred. The lime-salts appeared to have been deposited everywhere without any consideration as to the kind of tissue, and this was not materially altered by the process, as was shown on removal to the lime-salts. What appears to me to be peculiar in this case is, that two processes should go on alongside one another in the same organ, both neoplastic and yet having different results; in the one, resulting distinctly from ordinary fibrous tissue, a normal hyaline cartilage is formed—in the other, from sarcomatous cells, a kind of spurious bone is produced.

I have notes and specimens of a number of cases where true bone is developed by sarcoma-cells, and of others where various fibroid materials are formed by them, but I have not met with any case resembling the one I have just described.

The second tumor occurred in the human epididymis, and is of interest as being a pure chondroma in which every stage of development can be observed.

The tumor was large and nodulated, and on section showed the glistening appearance of cartilage. Under the microscope round or oval masses of hyaline cartilage existed among altered tubules. These cartilaginous nodules were in every stage of development, appearing first as small collections of cells similar to the mesodermic cells from which normal connective tissue is formed. In a further stage these groups had increased in size by the growth of the individual cells, and these had become oval or spindle-shaped, resembling the prochondral tissue in ordinary development. In further advanced nodules the cells had become more differentiated, and others showed the first formation of the capsule round each cell. In the next stage the nodules were similar to parenchymatous cartilage, and after this there was a gradual separation of the cells by the formation of a hyaline matrix, until a point was reached where the appearances were those found in fœtal cartilage.

The process had not passed beyond this stage, the hyaline matrix was perfectly homogeneous, and the cells irregular in shape, pointed or starlike, and the lacuna corresponded to the shape of the cell. In no part was there the regular form of lacuna and cell found in adult cartilage. It was difficult at first to make out the relation of this new tissue to the ciliated columnar cells of the tubes, but after careful search it could be seen, in many sections, that the growth commenced outside the membrana propria, and gradually grew into the tube, displacing the epithelium as it advanced. In some places the cartilage had grown completely round the epithelium and enclosed it, some of the columnar cells remaining in a

small space in the centre of a nodule of cartilage. In the majority of cases, however, the lining epithelium had become disintegrated, and was represented by a granular amorphous débris. Slight calcification had taken place in some of the cartilaginous nodules.

This case differs so much from ordinary chondroma of the testis, in the regularity of the process by which the cartilage is formed, that I think it will be of interest to morbid anatomists.

ANN ARBOR, January 7, 1889.

THE MEDICATION OF THE CERVIX UTERI BY MEANS OF SOLUBLE CAPSULES.[1]

BY H. A. SCHWENDENER, M.D.,

CLEVELAND, O.

WE can all recall the mental depression attendant upon the slow or indifferent results of our early attempts in the treatment of disease of the cervix uteri, and the disgust and self-distrust excited by the almost equally discouraging effects of our later and better planned efforts; followed in many cases by a lapse into a state of patient resignation to the caprices of diseased cervical tissues; and in not a few by a state of perpetual dissatisfaction with gynæcological work in general, and unsound cervices in particular. The most noted and successful of gynæcological authors and clinicians, while positive upon all points of pathology in these cases, and rich in therapeutic expedients, are compelled, even after making a favorable prognosis, to state that the duration of the case must be long and the treatment tedious.

For several years I have been in doubt as to whether the very slow, or even totally negative, results of non-irritating applications to the cervix uteri might not be due, in part at least, to failure of the medicinal agent to remain in contact with the diseased surface. Owing to the non-fixity of the uterus, contact with the vaginal walls is apt to remove a large proportion of any medicament applied to the surface of the cervix, and more or less of that which is left is very likely to be washed away by the local secretions. If a tampon is introduced with a view to preventing this, I am convinced that not infrequently, at the moment it is freed from the rim of the speculum and released from the forceps, it is given a push sufficient to send it into Douglas' cul-de-sac, carrying with it the medicine wiped from the very place where it is specially desirable it should remain. Occasionally, after adjusting a single tampon with special care, I have found, on examining the patient in the standing position, that the cotton but imperfectly covered the cervix. This gave rise to a feeling of doubt as to whether, when a single medicated tampon was used, it might not be displaced by the dry protective one placed over it, or pushed aside when the instruments were withdrawn; so for years I have carefully packed, or, rather, covered, the diseased surface with small medicated pledgets before placing the dry tampon, if such be required.

To be sure, there was no room for such doubt ten years ago, when, in accordance with the clinical teachings received in college, I habitually used a single tightly rolled tampon, large enough to uncomfortably fill the vagina, leaving no room for the index-finger to ascertain the state of the cervix after its introduction. A very few years showed the great superiority of soft, loose little cushions, easily adapting their shape to fit every curve and motion, over the large, firm, awkward props then used.

Perhaps others are more skilful than I, or less self-distrustful, and able to believe their tampons exactly in place, doing steady, efficient work till removed at the time specified. But, however efficacious the faith of the doctor in his remedies may prove in certain cases, certain am I that the duration of these troublesome cases of cervical disease was in no wise changed by my waking up to the fact, that placing a tampon in the neighborhood of the cervix did *not* insure prolonged contact of the remedial agent with the os externum.

For a year or so, covering the cervix with a medicinal paste, or smearing it with oil or vaseline to insure the adhesion of a powder, proved a great help to me, but now I find the application of soluble medicated capsules, fitting closely over the os, much more satisfactory; and until I devised these capsules, although my treatment of this class of cases was by no means unsuccessful, yet the results came so slowly as to be often discouraging. I am not aware that the duration of treatment was longer in my hands than in the hands of others, but now, after six months' experience in the use of a more certain and rational mode of treatment, the tediousness of the old seems to me almost intolerable. These capsules are made by Mr. L. E. Hinckley, of this city, and are one and one-fourth inch across, one-half inch deep, and being mainly composed of white wax and coca butter, melt slowly at the temperature of the body, keeping the medicinal agent for several hours in contact with the diseased surface. They may be easily introduced through an ordinary speculum, and once in position are not easily displaced, the warmth of the cervix causing close adhesion. I speak of introducing the capsules through an ordinary speculum, because, with the great majority of the profession, I am unable to always have a trained assistant at hand, and hence seldom use Sims' speculum. Indeed, I have several times satisfactorily placed these capsules without using any speculum at all (in cases where the vaginal orifice was very large), and have found them in perfect position after the patients have walked about the room, stooped, crouched, etc., and this, too, without a retaining tampon. A dry, non-absorbent tampon should, however, be used to insure longer contact of the medicine with the diseased surface, and to protect the clothing of the patient. I have removed such a tampon ten hours after introduction and found the capsule about half melted, and the whole cervix bathed in medicated oil. In from twenty-four to thirty-six hours after introduction the oil has been almost entirely absorbed. At this time a hot injection has a good effect. In one instance, in which two astringent capsules were used, after eighteen hours more than one capsule remained solid.

Since the middle of May I have used these capsules almost daily, and with the most gratifying results, especially in cases of old chronic erosions. In many cases no other treatment was used; in some I painted the cervix with iodine, or used a caustic application before applying the capsule; and very often used also a glycerine tampon. The formulæ used have been:

No. 1.	Iodoform.....	gr. v. in each.
2.	Iodoform.....	gr. iij.
	Tannic acid.....	gr. v.
3.	Ext. belladonna.....	gr. ½
4.	Ext. belladonna.....	gr. ½
	Opium.....	gr. j.
5.	Oxide zinc.....	gr. v.
	Bismuth subnit.....	gr. iij.

I am now experimenting with flexible gelatine capsules, but do not think they will be as efficient as those composed of wax and coca butter. Of course almost any formula may be used, or the action prolonged by using two of a kind, or modified by using one of each of two different kinds, or by covering with a medicated tampon.

At first, the question of how best to place the capsule was rather troublesome. Forceps would not hold without crushing it, and to simply put it in the speculum and push it along was not a very satisfactory procedure. I have had an instrument made by Mr. Baster, of this city, which proves quite satisfactory. It consists of a slender metallic tube, eight inches in length, set in a convenient handle, and surmounted by three flaring prongs. Through the tube and handle plays a rod with a ring for the thumb at its distal extremity, and surmounted by a small, flat

[1] Read before the Cuyahoga County Medical Society.

disk. This rod is drawn down, the capsule impaled on the prongs and carried to its place, when the disk is pushed against the capsule, loosening it from the prongs and pressing it more firmly against the cervix. The instrument withdrawn, the tampon may be placed and the speculum removed with the certainty that the therapeutic agent will remain where placed, and continue its action from twelve to thirty-six hours. As the instrument is as slender as Simpson's sound, it does not at all obstruct the view, and the prongs are so constructed as to easily pick up the capsules without the aid of the fingers. The advantage of this is obvious when we consider how tenaciously the odor of iodoform clings to the hands.

My office practice is almost entirely gynæcological, embracing, of course, a large number of cases in which applications to the cervix are necessary. During the last six months I have applied these cervical capsules in almost every one of these cases, and with far more positive and satisfactory results than I ever obtained from any other mode of treatment. Indeed, I am now able to cure in about one-fourth the time I used to find necessary, having reduced the duration of treatment from *months* to *weeks*. In short, the capsules are neat, convenient, inexpensive (costing only about three cents each), and very efficient.

ANEURISM OF THE ARCH OF THE AORTA: SUDDEN DEATH WITHOUT RUPTURE OF THE SAC. REMARKS ON THE CAUSES OF SUDDEN DEATH.[1]

By JOHN S. ELY, M.D.,

NEW YORK.

The patient was a woman, fifty-five years of age, a native of Ireland, and a washerwoman; admitted to Bellevue Hospital toward the end of October. For five or six years she had noticed occasional swelling of the feet. For six months she had suffered from dyspnœa on exertion, which steadily became worse. Cough for about a month. Two weeks prior to admission she had noticed a tumor at the root of her neck. Dysphagia had been troublesome for six weeks or so, and there had been some pain in the region of the tumor.

Physical examination disclosed slight emphysema and bronchitis; somewhat rapid and feeble heart, but no evidence of valvular lesion; liver and spleen normal in size. At the root of the neck on the right side, just above the sterno-clavicular articulation, there was a soft, compressible, pulsating tumor about the size of a small hen's egg. The pulsation was expansile in character, but there was neither thrill nor bruit. Pulse in both radial arteries was equal; also in both carotids. There was very marked atheroma of the arteries. Urine showed no albumen, but a few casts and pus-cells. Laryngoscopic examination disclosed paralysis of the right vocal cord.

Patient remained in much the same condition, with considerable dyspnœa and some cough, until the night of November 12th, when she fell out of bed in her sleep. She was helped back to bed by the nurse, who left her apparently none the worse for her mishap. In about fifteen minutes the nurse returned and found the woman dead, lying flat on her back, with no indications that death had been preceded by either pain or convulsion. The inference was that the aneurism had burst.

At the *autopsy*, performed fifty-four hours after death, the body was found to be well nourished. The brain was not examined. On opening the thoracic cavity a tumor about 3½ inches by 2½ inches was discovered, partly adherent to the manubrium of the sternum, and consisting of a dense sac of fibrous tissue containing an organized clot of considerable size, and some serous and bloody fluid. This tumor was found to originate from the arch of the aorta, where the ascending portion passes into the transverse. The innominate artery was incorporated in the posterior wall of the sac. The pneumogastric nerve of the right side was much flattened and involved in the wall of the sac. The phrenic and recurrent laryngeal nerves were also pressed upon by the tumor. The ascending portion of the arch of the aorta was very much increased in size.

Heart was somewhat hypertrophied, flabby, and showed no lesion on the valves. Lungs were normal, with the exception of much pigment. Liver was normal in size, but showed slight congestion and fatty degeneration. Spleen was hard and small. Kidneys were both rather small; capsules adherent; cortex thin, markings indistinct. Whole kidney quite red.

There was very marked endarteritis in all the main arteries, and an organized clot was found in the left internal jugular vein about the middle of the neck. There was no rupture of any vessel nor of the aneurismal sac.

The problems connected with the cause of sudden death are discussed with such vagueness in the text-books that I have thought it might not be uninteresting to the Society if I were to use this case as a text for presenting to its consideration some of the physiological factors involved, with a view to directing attention more rationally to the investigation of such cases.

It was long ago discovered that the heart of a frog could be removed from the body and still continue to beat rhythmically for a very long time, if kept in a warm, moist chamber. Latterly, Martin, at Johns Hopkins University, has shown that the heart of the dog may be completely cut off from all connection with the cord and brain—isolated, as they call it in Baltimore—and still continue to beat regularly for several hours, provided only that its nutrition be kept up by a continuous supply of defibrinated dog's or calf's blood.

These experiments show that the essential elements of the heart-beat are situated in the heart itself, in the frog and dog at any rate; and thus far, there is nothing known in human physiology which renders a similar arrangement in man improbable.

Investigation has shown that the parts of the heart necessary to its activity are the intrinsic ganglia and the heart-muscle. The heart of a frog may be cut up in small pieces, and the portions containing ganglia will continue to contract rhythmically, while the portions destitute of ganglia are perfectly quiescent, thus proving that the ganglia are essential to the beat. We must then look to the heart itself for the source of the trouble in cases of sudden death due to paralysis of the heart.

But may not sudden death be due to some other process than paralysis of the heart? I think not. I cannot conceive of it as the result of any other process than sudden stoppage of the heart, and I cannot conceive of sudden stoppage of the heart as the result of anything else than paralysis of the heart. It is surprising that "spasm" of the heart should still be spoken of in the text books. Physiologists have never been able to produce spasm of the heart, and pathologists have not shown how any such phenomenon is possible. Still, Gairdner, in the article on "Angina Pectoris" in "Reynolds's System of Medicine" (vol. iv. p. 579, 1877), says that opinion as to the cause of death in that disease is divided between "spasm" and paralysis of the cardiac muscle. In direct antagonism to such a theory of "spasm" of the heart, physiology teaches that each contraction of the cardiac muscle is simple, like the contraction of ordinary striated muscle caused by a single galvanic shock. The interrupted current when applied to heart-muscle produces, not a continuous ("tetanic") contraction, but a series of single rhythmic contractions. In other words, the heart cannot be put into a state of "spasm" by means of the most powerful neuro-muscular stimulant known to us, electricity. Let us then rule out "spasm" as a possible explanation of sudden stoppage of the heart, and consider the causes and effects of paralysis of that muscle.

Marked differences in the physiology of heart muscle and ordinary muscle certainly exist, but still there seem

[1] Read at a meeting of the New York Pathological Society, November 28, 1888.

to me to be sufficient points of similarity to make the pathology of the one very useful in the elucidation of the pathology of the other.

The essentials to voluntary motion have been found to be (1) the nerve-cells in the cortex of the brain, (2) the paths of communication between these and the muscles, and (3) the muscles themselves; and decided lesion in any one of these is attended with paralysis. In the case of the heart, we have seen that the intrinsic ganglia and the muscle are essential to the heart-beat, and we must of necessity suppose paths of communication between these elements. Reasoning, then, by analogy, we must conclude that paralysis of the heart would result from lesion in the ganglia of the heart, in the paths of communication between these and the heart-muscle, and in the muscle itself.

There are, then, theoretical grounds for the belief that lesions in the intrinsic ganglia and in the heart-muscle may be sufficient cause of paralysis of the heart. What has pathological investigation advanced in substantiation of this theory? Owing to the difficulty in finding the intrinsic cardiac ganglia but few observations of their disease are on record. Iwanowsky [1] has published the results of his investigation of the changes which occurred in them in a case of typhus fever. The nerve-cells in the ganglia were swollen and opaque, with indistinct nuclei; and in some spots well-marked degeneration of the cells was observed, as well as slight changes of an inflammatory nature in the connective-tissue stroma of the ganglia. Wassilieff [2] found decided changes in the same structures in hydrophobia. But the most interesting cases have been reported by Putjatin.[3] Only five cases of heart disease were investigated, but in all of them marked lesions in the intrinsic ganglia were found. The first of his cases bears directly upon the point under discussion. It was that of a man about forty years of age, in whom no lesion could be found to account for his sudden death except those in the intrinsic cardiac ganglia. The heart-muscle in this case is said to have been normal. The lesions found by Putjatin in these cases were hyperæmia, increased production of connective tissue, fatty and pigmentary degeneration of the ganglion cells, and in one case calcareous deposit in the connective-tissue stroma.

Although these are but few observations, too few alone to be sufficient foundation for a theory, still, in substantiation of a plausible theory deduced from other data, they are of the greatest importance.

Paralysis of the heart as the result of inflammatory and degenerative changes in the cardiac muscle, as, for example, the interstitial myocarditis so commonly found in cases of angina pectoris, is matter of too common observation to warrant further notice here.

But, it may be asked, if sudden death is simply due to paralysis of the heart-muscle, how is it that this comes on suddenly, paralyses in the skeletal muscles being so often slow in development? I answer that I do not consider paralysis of the heart to be always developed suddenly—far from it—and that in paralyses of the skeletal muscles we have occasionally a very rapid onset, for example, in infantile paralysis. Further, the conditions in the two cases are dissimilar. Whereas in the skeletal muscles the resistance to be overcome varies within very wide limits, in the heart-muscle it is practically always the same, variations in arterial pressure being comparatively very slight. In the skeletal muscles the power to move the limb is usually preserved long after distinct weakness can be determined, but usually there comes a time when this power to move the limb is lost too, and that suddenly. In the heart-muscle the rhythmic beat continues until a moment comes when the resistance can no longer be overcome, and when the heart-beat must of necessity stop suddenly.

It remains now to mention certain extrinsic processes to which sudden stoppage of the heart has been attributed.

There are in the central nervous system two mechanisms regulating the heart-beat, the one accelerating, the other inhibiting. Of the accelerating mechanism it is not necessary for us to say more than that its sole function, so far as known, is the increase in frequency of the cardiac contractions, and that it consequently has nothing to do with the subject under discussion. The inhibiting mechanism is, on the other hand, closely connected with it. The centre of this mechanism is located in the medulla oblongata, and is connected with the heart through the vagus nerve. Stimulation of the centre or of the vagus causes slowing of the heart-action, but, in order that complete stoppage be produced, the stimulus applied to the vagus nerve must be of very considerable strength and must be suddenly applied—very gradually applied stimuli, though of considerable strength, being ineffectual. For this reason it is thought that sudden stoppage of the heart as the result of stimulation of the vagus nerve by tumors must be extremely rare. In these cases the pressure upon the nerve must increase so gradually that entire disintegration of the nerve may be produced without sufficient stimulation to cause inhibition of the heart. In connection with the consideration of stoppage of the heart as the result of stimulation of the inhibiting mechanism, it must be borne in mind that the stimulus may be applied to the centre reflexly. The sudden stoppage of the heart obtained by striking a frog upon the belly is a familiar example of this, and all sudden death as the result of "shock" must be explained in this way.

The recurrent laryngeal nerve is an important path along which impulses may pass to the inhibiting centre in the medulla oblongata, producing sudden inhibition of the heart reflexly. This is, I think, the explanation of those cases of sudden death following instantly the lodgement of a foreign body in the larynx, to which reference was made at the last meeting.

In conclusion, then, I am of the opinion that the lesions which may cause sudden death should be looked for in, 1, the cardiac muscle; 2, the intrinsic cardiac ganglia; 3, the inhibiting centre in the medulla oblongata; 4, the vagus nerve; and, failing to find any adequate lesion in these parts, the possibility that death may have been caused by reflex stimulation of the inhibiting centre is not to be lost sight of.

Absorbing Power of the Normal Urethra.—Dr. Phélip has found that the normal urethra of the dog possesses the power of absorbing sulphate of atropine in solution, but that this absorption is much less active than generally supposed, and is not to be compared with the absorbing power of cellular tissue, and is but little more marked than that of the normal vesical mucous membrane, if both parts are placed in the same condition (*The Therapeutic Gazette*). In order to obtain equivalent results, the author has found that it is necessary to inject subcutaneously one-fortieth the amount injected into the urethra, while three or four times the amount injected into the urethra must be introduced into the bladder after it has been emptied to produce similar results. The absorbing power of the bladder is more marked when that organ is distended than when emptied. In the former condition it is about one-half as active as the urethral mucous membrane in the dog. Urethral absorption occurs principally in the deeper parts of the urethra.

In Tien-Tsin, China, according to the *Semaine Médical*, cholera is raging. The mortality of the disease is upward of sixty per cent.

A CASE OF ACUTE ULCERATIVE ENDOCARDITIS LIMITED TO THE TRICUSPID VALVE, WITH AUTOPSY.

By JOHN TRUMBULL, M.D.,

VALPARAISO, CHILI.

On October 23, 1888, I was invited to a consultation at the German Hospital of this city by the attending surgeon, Dr. Olof Page (University of Pennsylvania), whose interest and kind assistance have enabled me to report the case.

The following history was given: G. B——, an officer on a steamer plying between this and Hamburg, was sent to the hospital, October 19th, as a case of typhoid fever. He had been in capital health till within eight or nine days before reaching port, when he began to sicken with chills, fever, headache, inability to continue work, great weakness, loss of appetite, and slight diarrhœa.

Physical examination, made by Dr. Page on entrance, was mainly negative. Slight dulness was detected at both bases behind, but owing to the clear breathing sounds did not attract attention. The heart was normal, abdomen not tympanitic, no tenderness to be elicited on pressure, no gurgling or rose spots, but enlargement both of liver and splenic dulness. Since entrance the stools have been natural; and the only marked feature the distinct irregularity of the temperature, which twice or thrice in the twenty-four hours would shoot up to between 103.2° and 104.4° F. and after antipyrine drop to 98.6.° The urine had been normal in quantity, albuminous, but without casts or blood.

Two days preceding the consultation, Dr. Page, while making his visit, had been called to see the patient because of sudden dyspnœa and cyanosis. Nothing could be discovered to explain the condition. A provisional diagnosis of pulmonary thrombosis was made, and after the patient was bled and dry-cupped, nitrite of amyl, gtt. ij., was given in brandy every two hours. The following morning he was much better, though a similar attack came on later in the morning, and when we saw him together on the morning of the 23d he was in one.

Patient lying down, a strong, strapping man of twenty-eight years, profoundly cyanosed, not merely about the face and neck, for the entire body had a deep bluish look, teeth chattering, and bed shaking. The intelligence was clear and, so far as was possible under the circumstances, the patient gave a distinct account of his illness. Respirations 60, and labored; pulse 120, regular, but soft and small; temperature 101.4° F.; tongue moist and clean.

Careful examination of the chest revealed flatness at both bases, extending as high as the sixth spine, with absence of voice sounds and faint but clear respiratory murmurs. In the left infra-clavicular region a patch of dulness with diminished breath-sounds, without râles or alteration in pitch, was found. A hypodermic needle introduced in the left base immediately filled with pure blood. No increase in the area of cardiac dulness. Valvular sounds normal, with the exception of an altered systolic at the base over the left of the sternum, spoken of as a "probable murmur" at the pulmonary valves. No abdominal tympanites, no gurgling or tenderness, spleen and liver both considerably enlarged.

Typhoid fever was set aside, because of the absence of surroundings to account for it; absence, too, of the characteristic features, diarrhœa, tympanites, tenderness, hebetude, and chiefly because of the irregular pyrexia, frequent rigors, profound cyanosis and physical signs discovered in the chest examination.

Pulmonary thrombosis was excluded because of the repetition of attacks so severe that had the cyanosis been due to it death would speedily have occurred, and the failure of it to account for the small patch of consolidation, double pleuritic effusion, hemorrhagic in character, fever, enlargement of liver and spleen.

Acute double pleuro-pneumonia likewise we ruled out because we did not feel the effusion was sufficient to warrant such orthopnœa, even with the added patch of dulness that might be considered a centre of beginning pneumonia. Further, it would not explain the repeated chills, irregular and intermitting temperature, and it did not touch the enlarged condition of the abdominal viscera.

Intermittent fever was considered and thought to approach nearer than any affection considered so far to cover the case. There were enlarged splenic and liver dulness, recurring chills every morning, fever and sweating, but the fever continued after the attacks had passed away or recurred at irregular intervals during the day, the chest condition was unexplained by it, and it was inadmissible to suppose that, during a sea voyage, one who had not been off his steamer since leaving Hamburg could, in robust health, be stricken down with intermittent fever.

Acute miliary tuberculosis would cover loss of appetite, headache, prostration, irregular fever, and cyanosis, and chest signs with enlargement of liver and spleen; but there was no mere cyanotic tinge of finger-nails and lobes of the ears, rather a general deep cyanosis, no cough, no wasting, no strumous look, good family history. Mainly on the ground of repeated severe chills and his robust frame we agreed to exclude it.

The result so far was that the case could not be covovered by acute miliary tuberculosis, intermittent fever, double pleuro-pneumonia, or typhoid.

Ulcerative endocarditis we thought would explain the course of the disease, repeated chills, cyanosis due to minute embolic processes in the lungs, the patch of consolidation noted in the left front, the presence of fluid in the chest, the enlarged liver and spleen, and the presence of albumin in the urine. Against it were the fact that the hypodermic needle drew blood (I have since thought the needle must have penetrated the lung-tissue), the absence of a distinct murmur, of any irregularity of the heart's action, palpitation or pain, confirmatory of an endocarditis, and the absence of anything to have caused the development of the disease. The patient had never had rheumatism, nor had he any wound as a point of possible pyæmic infection. Still, as primary cases do occur, we thought capillary embolism of the pulmonary vessels, with consecutive sepsis and embolic trouble elsewhere, from disease at the valves of the pulmonary arteries, as most probable and of the nature of a malignant ulcerative endocarditis.

Morphia, one-fourth grain, was given to allay the distress arising from the rigor and dyspnœa, and quinine with stimulants were ordered.

October 25th.—Saw the patient to-day. not in a chill, but with extensive and pronounced cyanosis. Breathing 54, pulse 120, regular, soft, and feeble. Physical signs unchanged.

Temperature chart very irregular, between extremes of normal and 103° F. On the 23d had three heavy rigors, and four on the 24th. Has begun to cough since last seen, and is annoyed by it; no expectoration.

The marked recurrence and frequency of the chills led us to more confidently declare the case one of ulcerative endocarditis of the right side of the heart, and hopeless.

On the 27th as such we showed the case to another physician, who agreed with us as to the physical signs noted, though declaring his inability to detect any murmur. He sustained that we had to do with a case of violent acute double pleuro-pneumonia, with a tendency to emphysema. The chest was aspirated, and this time bloody serum having thick flakes of lymph was withdrawn, ten ounces from the left side and six ounces from the right. Relief very slight indeed, if any. Flatness diminished, but breathing sounds did not alter much. No adventitious sounds heard at the back, while a few moist râles could be detected over spot of dulness in left front. We could not accept the diagnosis offered and saw no reason to abandon that already formed.

October 28th.—Obstruction to the aeration of the blood,

it seems to me, continues the prominent feature of the case, with irregular temperature and recurring chills. Cough now is distressing, but no sputum is raised. To-day the only additional symptoms are a beginning œdema of the feet and a slightly dry, brown tongue. The therapeutic measures have been limited to the free use of stimulants and cardiac tonics. For the fever phenacetin (since the first attack of cyanosis it was used in place of antipyrine) is given whenever required, but while sometimes after its exhibition the temperature rapidly falls to normal, again it continues to rise despite its use, even in fifteen grain doses.

October 29th.—Patient much feebler. Pulse, 132; respiration, 62. Oppression so much increased that he cannot lie, but remains seated on the edge of the bed. Feet and lower legs œdematous and with purpuric spots, pin-head to pea in size, irregularly scattered over both upper and lower extremities. On the dorsum of each foot a larger patch of hemorrhagic extravasation. Has distinct icterus. Patient died in sitting posture at 4 A.M., on the 30th, and we made an autopsy the same day at 9 A.M.

Autopsy.—Strong, young subject in good condition, with extreme lividity of head and upper thorax. Over chest and shoulders slightly raised purpuric spots. Same condition in extremities with dark blue, deeper ecchymotic patches, irregular in shape, varying from bean to size of the palm and chiefly on the exterior sides; œdema of feet and lower legs.

Liver reached to within an inch of navel, and to the left as far as the mammillary line.

Opening the pleural cavities bloody serum escaped, estimated at twelve ounces or more from right side, somewhat less from left. Right lung shrivelled and shrunken with yellowish nodules visible under the surface. General roughness of visceral pleura and loss of glistening aspect. No adhesions except over an area size of a silver dollar where it was torn from the diaphragm. Lower lobe of right lung infiltrated in patches with reddish hepatization and multiple dull grayish-yellow spots of induration which on incision were found to be purulent foci. Left chest showed fresh adhesions on all aspects of the lung with the same general condition of embolic abscesses and here and there points of hemorrhagic infarction. Pericardium had a small amount of clear serous fluid, and over region of the tricuspid valve an elevation size of a thumb-nail was seen covered with a grayish-white opaque film. To the touch resistance felt from within like a nodule the size of a marble.

No enlargement of the heart. Left ventricular wall normal in thickness, cavity filled with soft, easily detached clots. Aortic and mitral valves intact and endocardium nowhere lacking in lustre. Right ventricle full likewise of post- and ante-mortem clots, a portion of which was with difficulty detached from the cordæ tendinæ. Opening the right auricle freely so as to look down on the tricuspid, two crumbly masses of vegetation, like two small flaps of warty growth, on the labia minora were seen, three-quarters of an inch long, one-half inch high, and flattened from side, to side looking upward toward the auricle, separating somewhat toward the remaining valve, which appeared wanting, while along the edge of its attachment to the heart-wall roughened spots with points of purulent matter were visible. The cordæ tendinæ were whole, and as seen from beneath the valves were intact. The vegetations grew from the auricular surface of the valves close to the edges, only two being implicated as stated, the third only having points of ulceration where closure made pressure against the verrucous growths.

Spleen large, pulpy, and very friable, weighed one and a half pound, without any infarctions or infective emboli. Liver enormously increased, weighing seven pounds, solid, firm, and of a grayish-yellow tinge—no abscesses. Kidneys slightly enlarged, capsules non-adherent. Removal disclosed pin-head yellow spots, small abscesses dotting the cortical substance. A wedge-shaped hemorrhagic infarction, size of a nutmeg, found in the right kidney.

Bristowe says, according to Bramwell, that "endocarditis and structural disease of the tricuspid valve are admitted to be so rare in the adult that there are few clinical or pathological records describing affections of that valve." This case is reported because of the rarity with which a primary vegetative endocarditis, limited to the tricuspid valves, is encountered, and the interest attaching to such a condition as described without the production of any distinct murmur. The growths must, it would seem, have prevented perfect closure of the tricuspid and yet the most thorough examinations, repeated, only gave a faint systolic blow along the direction of the pulmonary vessels leading out of the right ventricle. Osler says, that "even with extensive vegetations there may be no murmur present," as "there are many instances on record in which the examination of the heart was negative"; and this case must be classed among these, for the pathological conditions disclosed, one would have argued, must have given unmistakable physical signs, which were not present. Here we had an extensive verrucose endocarditis without auscultatory proof of its existence.

The diagnosis in this case was practically made by exclusion from an attempt to cover the whole set of symptoms. The pronounced disturbance with aeration when the respiratory sounds seemed clear pointed to occlusion of the pulmonary capillaries; and then we were driven to concede disease in the right side of the heart. That granted, and of the only form probable with the history, the consecutive pyæmic state covered the enlargement of the abdominal organs, while the passage of smaller emboli, through the pulmonary into the general circulation accounted for the albumen in the urine as due to metastatic abscesses of the kidneys. Only sixteen to eighteen hours before death did the manifestations in the skin, confirmatory of the diagnosis, appear; and throughout, from absence of cerebral symptoms, delirium, coma, or paralysis, one must infer that there was no embolic plugging or metastasis in the brain, as there was none in the liver and spleen.

Had one relied too implicitly and hurriedly on the results of the chest examination, to the neglect of the condition of the abdominal organs and urine, and the patient not been seen in one of the rigors, as the cyanosis was what absorbed the attention of the attendants, the case would very probably have passed for one of double pleuro-pneumonia. All cases of double or extensive disease should demand a thorough investigation, as to the possibility of their having a common cause in disease elsewhere.

Cases of ulcerative endocarditis, are generally classed as in type cardiac, intermittent, cerebral, typhoidal, or pyæmic. Here the irregular temperature, rigors, and metastatic processes would classify it as mostly resembling the pyæmic, though the pulmonary symptoms, dyspnœa and cyanosis, were the most pronounced and significant. In right-sided disease that would be expected, so that the pulmonary character, in the absence of any sign of valvular affection, would be the feature of its early stages, and only allow of its being classed as pyæmic in the advanced stages of the disease.

In this case the etiology is obscure. We had no antecedent rheumatism, recent or remote; no valvular disease; no trauma as a source of possible infection. The bacterial origin of the malignant form of this disease would seem to be well established; yet it must be past comprehension how a seafaring man, breathing the pure sea air, without any wound, in perfect health, should have had ingrafted on his tricuspid valves the staphylococcus pyogenes aureus. The position of the growth on the auricular surface of the tricuspid valves would imply that entrance must have been effected through the venous system. Careful inquiry failed to elicit any existence of wound; but having lately read of pyæmia as occasionally resulting from a urethritis, its existence was investigated, to see if even malignant ulcerative endocarditis might be attributed to infection along a mucous tract irritated by the gonococcus; but it was not present.

The case, therefore, one is compelled to admit as a case of *primary* ulcerative endocarditis, solely implicating the tricuspid valves.

Clinical Department.

CUPPING-GLASSES AS DIAGNOSTIC AND THERAPEUTIC MEANS.

By GEORGE WHITE, M.D.,

CHICAGO, ILL.

"Hues which have words, and speak to ye."[1]

When Otto von Guericke, of Magdeburg, invented his first toy hemispheres, it is probable that he never thought he was making that which would be sometime of inestimable value to the medical fraternity. However, the idea was put to a practical use in therapeutics, and the cupping-glasses became a part of the armamentarium of the barber-surgeons.

The use of these little instruments has fallen into decay, and it behooves us to resume their possession and assign to them their proper place in diagnosis and therapeusis. Advertising quacks in this city are forestalling the regular practitioners, and are making a good living by using the cups on all diseased (and supposedly diseased) conditions of our gullible sufferers.

So much attention is paid to new methods of diagnosis and treatment that many arts of fifty years ago are lost. Bleeding and cupping (which in the heyday of our fathers were the great routes to health in this life, or happiness in the hereafter) are now diagnostic and therapeutic means almost unknown. Bleeding is very properly eschewed in many diseases, but never have I seen ill result from the use of dry cups.

During the past six or seven years I have carried the glasses in my satchel, and upon every possible occasion experimented with them, to determine their utility in the exact localization of diseased areas; but among my medical acquaintances I do not know a single individual who does likewise. Yet these appliances are, I doubt not, more frequently needed than the much-abused obstetric forceps.

As diagnostic instruments the cups cannot do any more harm than the hypodermic syringe or the aspirator, nor so much as the probe, sound, or bistoury. As therapeutic agents their effects can be instantly controlled. Can this be said of the rest of our great army of remedies? What are the dangers of our numerous drugs? They are legion. What are the risks in dry-cupping? *Nil.*

I do not deny that the herb-teas of our grandmothers and the elegant preparations of to-day are valuable, but I do claim that many times they could be well replaced by these glass hemispheres.

In applying the cups to various portions of the body in disease I formulate the results of my observations thus: The greater the congestion at the point of contact the greater the cutaneous discoloration.

Often have I been enabled to accurately outline a congested area of deeply lying tissue by the aid of these instruments alone. Allow me to cite a few cases to illustrate the method of diagnosis, and at the same time to refer briefly to the accompanying therapeutic results:

In May, 1887, I was summoned to the bedside of a thirteen-year-old boy. He had just emerged from a severe general convulsion. The eyes were extremely bright and the skin had the peach-bloom of youth. A study of the family history elicited the fact that the father of the boy had died after an operation for renal calculi. My patient presented no genital trouble. Being of Jewish origin, he had been circumcised in infancy. Urination had been normal; defecation, ditto. He had received no injury by blow or fall. Deep pressure alongside the vertebra showed no tenderness except in the lumbar region. Opposite the tenth and eleventh ribs there was no special sensation. Over, or rather posterior to, the right kidney there was some sensitiveness. Posterior to the left kidney deep pressure caused intense pain. Application of the cups resulted as follows: At the first points there was a delicate pink hue. About the second location the color was a dark red. In the last position the flesh was almost black. It was a case of acute renal congestion. My patient regained his usual health in a couple of weeks. Another attack occurred in January, 1888, and yielded in a few days, as before, to the cups.

Another marked case was in a car-trimmer at the Chicago and Northwestern Railroad shops at Moreland, in this county. For several years the man had irregular attacks of deeply seated continuous pain in the lumbar region. One of our prominent West Side physicians had pronounced the trouble to be "neuralgia of the spine." The face was pallid and waxy in hue; eyes glistening. The patient complained that the upper eyelids seemed stiff and leathery in the mornings. There was almost constant nausea and recurring flashes of fever. Lately constipation supervened, but the urine remained normal in quantity, though a little high-colored. No microscopical urinalysis had been made till the cups had been used several weeks, and then, besides the large proportion of albumin and mucus, I could detect triple phosphates, a little pus, but no casts. Following the lumbar pains there had been sciatica on both sides. After a half hour's cupping the right renal region was a deep pink in tinge; left, dark red and covered with more deeply colored mottles, each about the size of two pin's heads. This half-hourly cupping was repeated twice each week. In two months the coloration after cupping was as follows: Right renal region, light pink; left, still mottled, but less marked than at first. Persistent prosecution of this procedure for three months cleared away the pain, dark coloration, and mottles. It was evidently a case of incipient lardaceous kidney. My patient is now doing his ordinary carpenter-work, and though he has an occasional return of his painful back when he exposes himself to inclement weather, he eats and sleeps like the average mortal.

Since November 24, 1888, I have been attending a lady suffering from fecal impaction of the colon, supervening in the course of a remittent fever. Her previous history, dating back to 1874, was as follows: Pregnancy, cystitis, parturition, laceration, ulcerations of uterus and urethra, fecal impaction of the colon, lumbo-pelvic abscess, fistulæ, surgical destruction of most of the recto-vaginal walls, chronic cystitis, etc. In this, the second attack of impaction, the cups were applied, and they told an odd story. Over the points of greatest continuous pain they caused a dark red tint, but the mottling showed most prominently along the left third of the transverse colon, the left curve of the colon, and the descending colon down to the neighborhood of the sigmoid flexure. This collection of mottles presented a very peculiar appearance, curving over the abdominal wall and being of a uniform width of about an inch and three-fourths, irrespective of the extent of surface embraced by the cups. During the first week the color in the left inguinal region was a very dark red; now it is a pearly hue while the glasses are *in situ*, but after their removal the natural tint appears.

A great beauty of this procedure in diagnosis is the simultaneous therapeutic effect. Five or ten minutes' application will give immediate relief in those slight congestions characterized by indefinite anterior and posterior thoracic pains that follow "taking cold." In a case of acute bronchitis, in a ten-year old boy, where the respirations numbered eighty-eight to the minute, I have seen immediate lessening of the dyspnœa, though the rapid respiratory act continued. Very frequently, in continuous, deeply seated pain, the cups are reliable substitutes for opiates, and never can produce the horrible results of those drugs.

A few cautions are necessary:

[1] Byron's Childe Harold's Pilgrimage, Fourth Canto, cxxix.

1. Use very little alcohol on the swab when about to burn out the air in the cup.

2. Do not keep a glass on the skin longer than two or three minutes at a time.

3. Avoid the edges of the scapulæ and ossa innominata.

4. Never place a cup upon the spinous processes of the vertebræ.

5. After each séance anoint the entire surface with carbolated vaseline, to prevent future superficial soreness.

As to the *modus operandi* therapeutically, I have no special theory. Sometimes the action seems to be by lessening the air-pressure on the tissue which covers the superficial capillaries, and consequently relieving the underlying congested area; sometimes it accords with our milder sedatives; sometimes the process seems to be wholly by mentality (?), like the darky's cure for the toothache, namely, put some red pepper in your eye and you will think so much about that eye that you will forget about the tooth.

However, be that as it may, there is a principle here involved, and we should not neglect it. It is our duty to ourselves and our patients to seize upon all means of exact diagnosis and rapid relief or cure. I offer these suggestions to my brethren to do with them as they will.

A NOVEL METHOD OF INTUBATION WITH ORDINARY RUBBER TUBE.

By GEO. O. WILLIAMS, M.D.,

GREENE, CHENANGO CO., N. Y.

Quite a number of fatal cases of diphtheria die in consequence of the obstruction to respiration caused by the closure of the fauces from tumefaction of the tonsils and uvula, the larynx at the same time being intact. The majority of those which fail within the first forty-eight hours are from this cause.

The case in question was of this character. The disease had existed forty hours. The child's age, eleven years. The fauces and soft palate were covered with exudation. The throat was closed. Respiration very labored. Constant restlessness had been present for thirty-six hours. All the indications of slow suffocation were present. The child was informed of what we desired to accomplish, and his promise to assist as much as possible was secured.

A soft rubber tube was then passed beyond the obstruction, and its extremity left just at the larynx. The boy nodded his head to indicate that it gave him relief and was in proper position. Within three minutes he dropped into a motionless slumber of absolute rest. The distressing breathing was instantly relieved.

The sleep continued an hour. At the end of that time a little mucus obstructed the tube, and he awoke and pulled the tube from its place. It was immediately replaced. The tube extended six inches from the mouth. An attendant constantly supported this extremity. An ink mark on it, on a line with the teeth, designated the proper distance for introduction. After a few hours the care of the tube was intrusted to the friends. It was maintained in use for seventy hours. It was removed for cleansing, and for nutrition and medication at proper intervals. At the end of that time the subsidence of the tumefaction permitted its discontinuance. The tube measured seven-eighths of an inch externally. No complication occurred in the case and a good recovery followed. I do not recall any published account of such a procedure in diphtheritic cases, but I think quite likely, from its simplicity and efficiency, that it must have been in use by others.

The "Funny Bone."—*Teacher:* Why is the arm bone called the humerus? *School Girl:* Because it has a funny bone.

Progress of Medical Science.

Case of Traumatic Aneurism in a Child under One Year.—The patient, a girl, aged eleven months, while at play, fell upon the floor, sustaining a bruise on the left cheek, which was followed subsequently by the development of a large pulsatile tumor of the size of a hen's egg. The health of the child in no way suffered from the swelling until one day when she accidentally scratched the skin covering it with her nails; inflammatory symptoms supervened, and a medical man ordered poultices to be applied, subsequently puncturing the tumor. Alarming hemorrhage followed the puncture, which could not be controlled. When Mr. Bose, who records the case, was summoned, he found the child almost bloodless. The dressings were removed from the wound and the clots turned out; a small branch—the malar—of the facial artery was feebly spouting, and was at once twisted. The soft parts around the wound were sloughy. The following morning it was seen that the hemorrhage had still continued; the sloughing process had spread to the outer canthus of the eye. A consultation was held, and it was decided to adopt further measures. The facial artery was tied, the inflamed tissues were freely incised, all the clots were removed, and the wound dressed with boracic ointment. The hemorrhage ceased from this moment, but the child succumbed after three days.—*Indian Medical Gazette.*

Tumor of the Brain and Accidental Injury.—The following case, observed by Dr. Kaufmann (*Vierteljahrschrift für gerichtliche Medizin*), is interesting chiefly from a medico-legal point of view. A house painter was thrown from a ladder, striking in his fall the corner of a piece of furniture. From this time on violent headaches and pains in the back were frequent. Immediately after the fall he remained several hours unconscious. After slight and transitory improvement, during which he returned to his work, the head pains returned, mental weakness, slowing of pulse, narrowing of the field of vision, and loss of appetite came on. Transitory mania was also observed during the cephalalgic attacks, finally almost total blindness and paralysis of the left arm supervened. Death took place six months after the accident. Post-mortem examination showed death to have resulted from a sarcoma. The tumor was of comparatively recent growth; the oldest pathological cerebral lesion was evidently an apoplectic cyst which was surrounded by a cheesy tumor. This cyst was pronounced by the pathologist to correspond to an effusion of blood of such amount that it could not have taken place without visible symptoms. It was extremely probable that the hemorrhage was the result of the fall, and that the loss of consciousness noted was dependent on it. The hemorrhage was the direct cause of the development of the tumor, as injuries, falls, and the like were undoubted and recognized causes of cerebral tumors and their most frequent explanation, especially in the case of sarcomata. All other explanations were only hypotheses. The histological examination of the tumor explained its rapid development in so short a time. The conclusion was that the fall led directly to the development of the tumor, and through this to death.

Unilateral Kidney and Nephrectomy.—Cases have been recorded before now in which, after removal of a diseased kidney, it has been discovered that the organ was the only one of its kind, a fact which naturally is not without its influence on the success of the operation. At a society meeting last week, by a curious coincidence, two kidneys, from different subjects, were shown, one of which had been removed post mortem from a woman who had been operated on for ovarian tumor, and which proved to be unique, no trace of the other kidney being found. The second had been removed on account of kidney disease, and was therefore a nephrectomy proper. If the con-

dition which obtained in the first case had existed in the second, the operator would evidently have been unable to report that his patient was enabled to leave the hospital, well, within a month. The very practical question arises, therefore, as to the means at our disposal for recognizing the absence of one kidney before proceeding to remove the other. Many surgeons advocate the performance of the operation through an incision in the median line of the abdomen, since it is then possible to ascertain the presence and condition of both organs. Dr. Fenwick claims that nothing is easier than to watch the flow of urine through the ureter into the bladder, thus affording proof positive of the existence of a duplicate secreting organ. It was pointed out that nephrectomy would only be undertaken for grave disease of a kidney, and were this kidney the only one, symptoms pointing to disease of both kidneys would probably be present. To put it another way, if a patient with serious disorganization of one kidney presented no general symptoms of uræmic intoxication, it might reasonably be assumed that excretion is being carried on by the other organ. Since the result of an error of this sort is the prompt and inevitable death of the patient, the matter is deserving of every consideration.—*The Medical Press.*

Partial Resection of the Symphysis Pubis in Operations at the Bladder.—Dr. Helferich in three cases has removed a portion of the symphysis pubis in order to afford readier access to the bladder. In one case the condition necessitating the operation was tuberculous caries of the symphysis itself. In the others it was carcinoma of the bladder, and great enlargement of the middle lobe of the prostate. He recommends a partial resection as giving sufficient room in most cases without interfering with the solidity of the pelvis. He makes a transverse incision and pushes back the soft parts. He pays but little attention to the periosteum, except that at the lateral portions of the pubis which are to be retained. He thinks it useless to attempt an osteoplastic resection of the symphysis, as frequently, in the cases in which this operation is done it will be found impossible to close the bladder wound. After reaching the bone he divides it on either side to the necessary depth, perpendicularly, with a broad, sharp chisel; and then placing the chisel horizontally at the required level, and beginning at one of the perpendicular lines, he divides the symphysis from before backward, carrying the chisel from each end of the exposed bone toward the centre. The upper portion of the symphysis thus loosened is easily removed. In the case of caries, complete union occurred in two months. The case of carcinoma of the bladder showed the great advantage of this method, giving free access to the tumor, which was upon the upper aspect of the posterior wall, and was excised together with sound tissue on either side of it. The bladder wound was sewed with catgut stitches. There was considerable strangury for a few days, but it gradually diminished, and healing was complete in three weeks. His case of prostatic enlargement died eight days after the operation, but was a very unfavorable one from the beginning—having had retention of urine, urethrorrhagia, etc., for some time previously. He considers the procedure an easy one in all respects, and one that can be completed in a few minutes, but recommends preliminary practice on the cadaver. The indications for the operation are large malignant tumors, some forms of prostatic hypertrophy, excessively large stones or encysted stones, cases of rupture of the bladder, etc.—*The American Journal of the Medical Sciences*, December, 1888.

Lipanine.—Lipanine is the name of a mixture of olive-oil (100) and oleic acid (6), which has been largely experimented with by Mr. Mering as a substitute for cod-liver oil. It is said to be far more digestible than the fish oil, and is taken by children without repugnance and without subsequent ill effects. The dose is from one to four teaspoonfuls, according to the patient's age, and the patients to whom it was given all improved in general condition and strength. The effects were altogether comparable with those obtained with cod-liver oil, but the advantages claimed for lipanine are its freedom from taste and easy toleration by the stomach.—*The Medical Press.*

Primary Nasal Diphtheria in Children.—Dr. Somma states that nasal diphtheria rarely occurs as a primary affection, though it is common enough as a secondary development from the pharyngeal form. He believes that when it occurs primarily it is usually an indication that there has been general infection of the organism, the local eruption being one of the symptoms. The varying degrees of severity of the disease are explained by difference in potency of the infective agent, and to this may be added the varying degrees of resistance of the tissues to the localization of the disease, and the varying degrees of resistance of individuals to the infective agent. The author believes, however, that in all cases of diphtheria which are primarily nasal, whether light or severe, there is an expression of a diphtheritic general infection. Age and sex have nothing to do with this localization of diphtheria. On the other hand, on account of the abundant blood-supply in the nose, on account of its continual contact with the air, and the infectious elements of the latter, which, suspended in the nasal mucus, are often in contact for a long time with the nasal mucous membrane, it is especially predisposed to the reception of infection. There is nothing peculiar about the anatomical condition of this variety. Symptomatologically it may be divided into a mild and a severe form. The former is without fever, without great disturbance of the general condition, and is characterized only by the presence of the local deposit in one or both nostrils. The severe form always has a preliminary febrile stage. At first there appears to be only a simple catarrhal coryza, but soon membranous deposits appear upon the nasal mucous membrane, the submaxillary glands swell, there is cough with occasional attacks of suffocation, the eyes and ears are involved, while the pharynx and larynx remain unaffected. In some cases the patients die after a few days with symptoms of general sepsis, in others the exudate is eliminated and recovery occurs, or the general symptoms remain in spite of local improvement and the cases end fatally, or the process may attack neighboring organs with an equally fatal result. The diagnosis is usually easy, excepting in rare cases in which the deposits are located so far back in the nasal cavities that they are not discovered. In such cases rhinoscopy is sometimes of avail in not very young children. The prognosis in the mild form is good, but in the severe form very bad. The treatment consists in irrigation of the nose with salt water, or one per cent. solutions of resorcin or salicylic acid, in the introduction of iodoform-vaseline, one to twenty, or in the insufflation of benzoic acid, alum, and tannin. Injections may also be made every three hours with solutions of acetic acid, lactic acid, or sublimate, one to four thousand. In the latter stages of the disease ointments of white or red precipitate may be used. Internally the carbolate of quinine in small doses may be given, and stimulants if collapse appears imminent.—*The Archives of Pediatrics*, December, 1888.

The Diagnosis of Inebriety.—All cases of inebriety may be classed as persons of undeveloped, degenerate, and disordered minds. The first class, the undeveloped, represents all grades of defective retarded growths, sometimes seen in external conformations of head and body. Grades of ancestral defects and brain failures, seen in faulty acts and thoughts. The second class, of degenerate brains, are those who are retrograding both in mind and body. Such cases frequently date from illness, injuries, shock, diseases of all kinds, and diseases of old age and of the nerve-centres. The third class, the disordered brains, are those who from ill-health, bad conditions of living and surroundings, have developed inebriety. Such cases cannot bear the strains, drains, or any extreme

circumstances which tax the energies and vigor of the body. In all these cases inebriety starts from unknown states and exciting causes, and these marked physical conditions are both primary and secondary. Inebriety is always disease and degeneration, and the fact often disputed is, can this disease be traced in any uniformity of symptoms or progress? Dr. Jackson has clearly pointed out that all disease follows a regular retrograde march, which can be outlined and studied as clearly as growth and development. Inebriety is no exception to the rule. —*The Quarterly Journal of Inebriety.*

CANCER TREATED BY CREASOTE.—Neudörfer has just published an interesting little pamphlet on the subject. Carcinosis, the author says, is very probably just as curable as syphilis or phthisis. The excision of a carcinoma, as of a hard chancre, is, as a rule, not far-reaching enough to prevent the infiltration of the surrounding tissues with the specific microbes and cells. He believes that the medicinal treatment of cancer should be tried more extensively than has been the case hitherto. The rind of condurango and Chian turpentine have often given promising results. There are also, as in phthisis, climates favorable for cure. On the plateau of Mexico and at the Cape of Good Hope, for instance, cancer is an exceptional disease. The principal office for the surgeon, in Neudörfer's opinion, is not the extirpation of the neoplasm, but the medicinal treatment of the cancer cachexia, which is the chief factor in bringing about the death. The treatment of cancer is naturally much like that of phthisis. Creasote, which has been found to stimulate the nutrition of the blood-corpuscles, is of equal value in cancer and in phthisis. He has obtained decided results in the treatment of cancer with the following preparation:

℞. Creasoti puri,
Sodii bicarb.,
Olei morrhuæ.....ää f. ʒ v.
M. Put in 100 gelatine capsules. Take three capsules three times daily, after each meal.

A very eligible substitute for creasote is creolin, as it is not only cheaper than the former, but is also a stimulant of digestion. He prescribes:

℞. Creolin..... ℳ xv.
Ext. glycyrrhizæ, q. s. ut ft. pil. No. 100.
Sig.: Three pills, three times daily.

Locally, Dr. Neudörfer prescribes with the above pills:

℞. Creolin,
Ichthyol,
Iodide of potash.....ää gr. xj.
Vaselin,
Lanolin.....ää gr. xv.
M. F. ung. Sig.: Rub into the part three times daily.

Neudörfer boasts of three actual "cures" of cancer obtained with this treatment.—Cor. *Medical and Surgical Reporter.*

INTERMITTENT HYDRONEPHROSIS.—Dr. Landon has published a study of this subject, which is alluded to by the *Medical Press* as follows: He remarked that the disease was rare, but that it was known and mentioned as far back as 1650 by Tulpius. Other authors have also mentioned this curious condition. The case brought forward by him in 1880, in which the hydronephrosis turned to a pyonephrosis and left behind a renal fistula, was the ninth recorded case of the kind. He had since then observed four other such cases. By intermittent hydronephrosis he understood that accumulation of urine in the pelvis of the kidney, from some undefined cause, relieved by sudden emptying, and subsequently recurring. In his cases the hindrance to the proper outflow of urine was only imaginary. The most remarkable kind is that accepted in literature as bilateral spasm of the ureters that causes anuria. He said he had observed spasm of a similar kind in the dead body in attempting to pass hot water through the ureters. The ureter contracted so firmly that not a drop of fluid could be induced to pass. There were, however, two other kinds of occlusion, one from direct dragging and pressure of the ureter against the pubic arch, and the other from acute flexion or twisting of the ureter, or from insertion at an acute angle. As regarded the first kind, Virchow showed, in 1846, that a prolapsed and irreducible uterus had so pressed the ureter against the pubic arch that the ureter and pelvis of the kidney were distended with urine. The patient died of uræmia. Another case of double hydronephrosis showed that it must have been intermittent, or the patient could not have lived as long as she did. He had not yet succeeded in demonstrating this obstruction *intra vitam*. The second form of obstruction was frequent enough, as Cohnheim had shown. The stasis of urine persisted as long as its cause, and then the collected fluid flowed off. This was repeated so often that the elasticity of the pelvis of the kidney began to suffer, and it finally attained such a size that the tumor had even been mistaken for one of the ovary. The question arises as to how acute-angled insertion takes place. Virchow considers that it was congenital; Simon held it to be a necessary consequence, and he showed that when hydronephrosis takes place and the insertion of the ureter is not in the first place acute-angled, the ureter must take an acute-angled course and suffer lateral pressure from the gradually enlarging renal pelvis. The acute-angled insertion could not be congenital in the majority of cases, but it was remarkable that the affection was most frequently on the right side; and this was in favor of the assumption that the acute-angled insertion was acquired, and indeed produced by a movable kidney. The kidney sinks, and the hydronephrosis is caused by acute flexion or twisting of the ureter. The symptoms in his five cases were fairly constant; nothing was remarked except slight attacks. They all complained of occasional uneasiness, and of the feeling of a foreign body, but nothing as to the urinary function. One patient complained of attacks resembling renal colic. The objective symptoms were not striking at the commencement. Only when the tumor could be diagnosed an intermitting hydronephrosis might be assumed. As regarded palpation, fluctuation could not be detected in his cases, but the tumors were remarkably hard. Puncture was not always reliable, as the contents of the hydronephrotic sac did not always contain urinary constituents. After a certain time these were reabsorbed, and nothing but clear watery fluid like that met with in the case of echinococci was found. In two cases he discovered urinary constituents—in one urea and in the other uric acid. As regarded treatment, he observed that if he was opposed to nephrectomy in permanent hydronephrosis, he was still more so in the intermittent form, as one could entertain the hope that, after emptying the sac, further flexion of the ureter might be prevented by support and rest. The disease, however, might become pyonephrosis, and if the other side then became affected the patient was irretrievably lost. When, therefore, the symptoms were grave, fear of operation should not deter one from acting. Excision of the kidney should not, however, be the first choice. There are two methods of treatment; one was the formation of a fistulous opening. One of his patients had had such a fistula for eight years, and was quite well otherwise. In a second case the fistula closed and the patient was free from her hydronephrosis. Hahn's proposal was to stitch the sac as high in the abdomen as possible. A third method was put into practice by two of his patients. By lying in a suitable position, or by kneading, they succeeded in completely emptying the sac into the bladder, so that after passing all the urine they were able to do, by pressure on the tumor they were able to force another like into the bladder.

DR. SCOBY, of Brussels, to whom had been awarded the prize, offered by the Royal Academy of Medicine of Belgium, for the best essay on the dietetic treatment of disease, died a few days before the announcement of his good fortune.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 26, 1889.

MEDICAL PROSPECTS AND BRITISH WAILS.

THERE are medical pessimists enough and to spare in our country. They are the ones who never weary of looking upon the dark side of all that pertains to the American medical profession, often forgetting that where there are deep shadows there must needs be bright light somewhere. It may afford these malcontents some satisfaction to know that "Old England," too, is by no means without its quota of dissatisfied, disappointed, and disturbed ones.

Indeed, if one has a taste for dismal forebodings, complaints, and lamentations, the medical literature of the entire world will afford ample opportunity, just at present, to satisfy the keenest appetite in that direction.

Some recent British wails illustrate this phase of professional life rather better than anything that has lately come to our notice. Under the caption of "The Protection of the Medical Profession," a correspondent of the *Lancet* writes that the profession ought to take steps to protect itself. He says that "the onus lies on the rank and file of the profession to take action, for if some joint and hearty action is not taken, we had better let things remain as they are, and be content to grin and bear it. I myself have had now over a quarter of a century's hard work in the profession, and I have only to look back and contrast the present state of the profession with its state twenty or thirty years ago to see how it has fallen in status. Acts are now unblushingly done which no gentleman would have dared to do in former times. Further, we see, owing to the unnecessary competition, the beneficent influence of sanitary science, and other causes, our emoluments gradually year by year getting less, while every day numbers beyond the real wants of the public are crowding into the profession, and so reducing incomes to a starvation point. I could bring forward endless grievances and abuses as they now exist, etc. If any reasonable number of the profession will help me, I will try to establish a league to bring about a more healthy state of affairs, so that we may happily become again a body respected and remunerated as we once were—a state of matters that will be for the joint benefit of us as a profession and of the public at large."

This writer is certainly very much in earnest, and the state of affairs pictured by him is not a pleasant one to contemplate, provided always that it represents the truth.

"Medicine as a Career for Young Men," is the title of an article by Mr. Crespi, published in *The Medical Press*, and if the author had called it "A Warning to Young Men not to become Doctors," the title would have conveyed his true meaning far better than the one under which he writes. He states that "the medical profession attracts, for obvious reasons, fewer of the very rich men who in considerable numbers enter the law, the church, and the army, nor does it obtain nearly so many men of good family and superior education, the latter shown by a distinguished academical career, as the bar and the church, though, at the same time, a large proportion of doctors have been decently and respectably born and educated."

He then shows all the difficulties in the way of success for the young practitioner. For example, he takes the "most favorable, though necessarily a small class, those young men who, after a long, costly, and successful curriculum, have obtained the best diplomas, and may also possess such academic distinction that a brilliant career seems to be before them. Unfortunately, with the constant improvement in the education and attainments of the rank and file of the profession, there is less demand for consultants than formerly; the provincial towns of the second and third class do not offer the field they once did, and a well-established professional reputation is more than ever essential. For consultants a brilliant reputation is needed, and without it little can be done. How is the young physician or surgeon of twenty-five or twenty-six to make that reputation which will alone bring him well-to-do clients? If he aims high, his chances of failure are many, and without the possession of money it is an absolute impossibility that he can help failing. He gets, we will suppose, some honorary hospital appointment—London or provincial—and determines to work hard and to achieve success. He cannot advertise, the public does not know him, and his own profession will not help him. He must live in good style, among his equals, and take only large fees. His success is thus extremely doubtful, and though an uphill fight of twenty years might in some cases lead to a flourishing position and a good income, many men fail to achieve success, do what they will, and not a few die dispirited." He has "known men of great ability who had to fill house-surgeoncies, and to pick up a miserable living from writing, tuition, or, indeed, from anything for the first dozen years, until they could get some valuable stepping-stone or scrape together money to pull on for a few years."

In *The British Medical Journal*, *The Provincial Medical Journal*, in a word, in all the leading English journals similar complaints occur again and again. And here, finally, is what the pungent pen of "Peripateticus," in *The Hospital Gazette*, has to say on the occasion of the recent opening of the London winter session, as regards the prospects of the British medical career: "I should be only too pleased on the present occasion to congratulate the hundreds of new students who will read these notes to-day on having chosen medicine as a profession could I honestly do so, but I regret to say that I cannot. Only a few years ago to possess a medical qualification was to command respect, position, and most probably wealth. In a few years all has changed. The profession is frightfully over-crowded, and it would not be exaggeration were

I to say that there are now hundreds of well-qualified and able doctors almost reduced to beggary. Twelve or fourteen years ago sixpenny dispensaries were known only to the lowest costermonger districts of the metropolis. Now they swarm all over London, and seem to thrive well even in the most aristocratic parts of the West End. Consequently doctors who conduct their practices on the old lines find their incomes falling off, and many are in dire straits."

Surely our British confrères are in no enviable position, if all these complaints are well-founded. But we venture to believe that the picture has been overdrawn. Hard work is necessary nowadays if success is to be obtained in any profession, but when energy is coupled with the requisite ability the outcome should not be doubtful. Dunces, idlers, and even those handicapped by some physical weakness, are certainly ill-advised to choose the medical profession for their life-work. But the absence of the necessary qualifications to make a prospectively useful physician ought to be apparent before the termination of the medical curriculum.

Moreover, we cannot help believing that the English writers quoted above have taken a rather one-sided view of what constitutes "success," making it tantamount to growing rich by the practice of medicine.

For their benefit we may be permitted to reproduce a few sentences from a recent address by Dr. Joy Jeffries (*The Boston Medical and Surgical Journal*). He very aptly points out that, "it is useless for us to contend with trade or business, either in earning a living or in the accumulation of money. Our profession is most essentially not a trade. Those in it who attempt to make it so but lower themselves to the level of trade, or simply money-making. Our calling belongs to that department of man's work recognized as scientific, or knowledge-seeking. We are simply men of science, that is, men of knowledge and its pursuit, the attainment of which is to benefit other people primarily. Now, the world over, men who give themselves up to the pursuit of knowledge have been considered as worthy of only so much of this world's goods as will simply keep them bodily in a condition to work with their brains and hands in science seeking."

And continuing, he says that "the young man in this country who wants to go into medical trade, thinks he has only to learn a little and get his diploma as he would fit up a grocery shop. The community thinks so, too. The so-called medical colleges scattered over the country are ready to help him for the fees he can scrape together to pay them. This tradesman opens his shop for custom, and the world looks upon and patronizes it like any other shop. But in medicine, as in all the true professions, work but commences with the responsibility of occupation, and never ceases while that lasts. Better for a man if it lasts through his life."

THE SURGICAL ASPECTS OF DIABETES.

The question of the propriety of surgical operations upon patients suffering from diabetes has received considerable attention of late years, yet it is by no means to be regarded as closed. It is known that diabetics are very prone to septic infection, and it was at one time thought that this was of a specific character, due possibly to the presence in the blood of a peculiar poison. It has been shown, however, that this view is erroneous, and that patients of this class are more liable to suffer from septic infection simply because the secretions are so altered as to offer a favorable soil for the lodgement and growth of the specific micro-organisms. On the strength of this theory it has been asserted that operations upon individuals with glycosuria are no more likely to be attended with unfavorable results, provided strict antiseptic precautions are taken, than are operations upon non-diabetics. That this confidence is not justified by facts, must, however, be admitted, notwithstanding the reports appearing from time to time of successful results following major operations in patients of this class.

An instructive case is reported by Dr. Alfred Hoffa, in the *Münchener Medicinische Wochenschrift*, No. 51, 1888, which would seem to convey the warning that it is unsafe to operate, not only on those whose urine contains sugar, but also on those who have been apparently cured of their trouble. The patient was a man, sixty years of age, who had suffered for some years from diabetes and albuminuria. He had been treated at Carlsbad, and for the past two years had passed no sugar in his urine although there was still a trace of albumin. He consulted the reporter on account of a cancer of the rectum. Examination of the urine at this time showed not a trace of sugar and but very little albumin. As the patient's general condition was excellent an operation was advised, and the new growth was removed. The immediate results of the operation were good, the patient recovered promptly from the anæsthesia, he had a full and strong pulse and no fever, the wound behaved well and there was at no time any sign of septic infection.

Despite these apparently favorable conditions, however, the patient did not do well. An examination of the urine, drawn by catheter on the evening following the operation showed, to the author's surprise, 2.4 per cent. of sugar. During the night the patient was very restless and seemed to be suffering from iodoform-poisoning. The next morning the sugar was again absent from the urine. The iodoform dressing was removed and sublimate gauze substituted. During the three following days the urine contained considerable iodine, but no sugar, and the patient seemed in a fair way to recover. At the end of this time, however, as the iodine began to disappear the sugar returned. The man soon after this became comatose and died.

There are two interesting points in this case. The first is that to which we have already alluded, namely, the reappearance of sugar in the urine immediately after the operation, although there had been no traces of it for the two years preceding. Whether it was due to the effects of the anæsthetic or to those of the operation might, perhaps, be a subject for discussion, but it is altogether probable that the operation, rather than the anæsthetic, was the exciting cause, and, in either event, since the anæsthetic almost necessarily accompanies the operation, the case illustrates the danger of performing an operation of any magnitude upon the subjects of diabetes, even after a so-called cure has been effected.

The second point worthy of mention is the apparent influence of the iodoform upon the excretion of sugar.

Immediately after the operation the urine contained sugar in considerable amount, but coincident with the symptoms of iodoform poisoning the excretion of sugar ceased, and began again only as the effects of the iodoform gradually subsided. Moleschott has recommended the drug as a most efficient remedy in diabetes, and Dr. Hoffa's case would seem to confirm this opinion. It is rather to be regretted that the author did not resume the iodoform dressing, in view of its favorable action upon the diabetes; but he states that he feared to do so lest he should kill his patient, a somewhat similar case, reported by Rinne two years ago, having terminated fatally from iodoform-poisoning.

A HEALTHY CITY IN AN UNSANITARY CONDITION.

IT is rather late in the day to ask if sanitary measures really limit disease in populous cities, for the experience of mankind has emphatically answered that they do. Yet it is well to remember that a city can never be kept perfectly clean, and that probably we shall never be able to stamp out zymotic disease wholly, or absolutely to prevent epidemics by these means alone. However pure and clean a city or a community may be, there is always a chance for some focus of infection to remain for a time undiscovered, and for the germs of disease to be scattered. On the other hand, a city may be in a most foul condition, every sanitary law seeming to be grossly violated, yet the death-rate is not large, and epidemics visit it no more frequently than they do other cleaner, and one would suppose therefore more healthful, communities.

An example of this is furnished by the city of Canton, where the first effort in the direction of sanitation, as the term is understood by western nations, has yet to be made. A writer in the *China Medical Missionary Journal* draws anything but an inviting picture of the city. It has, he says, an estimated population of 1,500,000, occupying an area of four and a half square miles. There are several canals running through the city, which are the receptacles for all sorts of offal and filth, fecal matter excepted, and at low tide their bottoms present miles of decomposing animal and vegetable matter. There are no drains in Canton, but in most of the streets are ditches about two feet wide and deep, loosely walled up with brick and covered with stone slabs. The streets are nearly level, and thus there is barely any fall to carry off the water. These ditches are seldom cleaned out, and are usually choked with refuse from the street and houses. On the sides of many of the streets are also uncovered ditches filled with stagnant water and filth. Either in the courtyard or in the rear of each house is a cess-pool, which is rarely cleaned out, and is usually in the same condition as the street ditches just described. The greater part of the water-supply "is derived from wells, which are from four to fifteen feet deep, and, of course, contain nothing but surface-water. A great part of this surface-water is the refuse-water which has been used by the million and a half people occupying four and one-half square miles. It percolates through the filth of the sinks and ditches, and then through soil which has been saturated for centuries with animal, vegetable, and saline deposits."

There is one good feature in respect to these cesspools and ditches, and that is that they receive no human excrement. Owing to the agricultural necessities of the people urine and fæces have a market value and are carefully saved and sold for manure. This, doubtless, is an important factor in the reputed healthfulness of the city. The writer above referred to has resided for more than thirty years in Canton, and he asserts that the city is not more unhealthy or more subject to epidemics than western cities generally. Statistics of mortality are, of course, wanting, so that it is not possible to speak with accuracy, yet a medical man, after a residence and practice of a quarter of a century in a city is in a position to judge with tolerable correctness of the general mortality-rate among its inhabitants, and of the extent to which it suffers from epidemics of disease. Epidemics, of course, prevail at times, but not in more violent forms than in the cities of Europe and America.

There are three principal factors at work in preventing Canton from being the pest-hole which it ought to be in the absence of any regard for sanitary matters. The first of these is that above mentioned, that little or no contamination of the soil by human excrement occurs. The second is that the people pass an active existence, and, the weather being warm, live for the most part with open doors and windows. The third, and most important, is that all the water that is drank is taken in the form of tea, and is consequently boiled, and the food is also, as a rule, thoroughly cooked.

News of the Week.

ONE GOOD TURN DESERVES ANOTHER.—If the *British Medical Journal* is compelled by its council to apologize to Von Bergmann for publishing the Emperor Frederick's script, "Bergmann ill-treated," one naturally wonders if the German physicians who wrote their report attacking Mackenzie should not also apologize. It appears to the impartial observer that both publications were unwise and indiscreet.

WE LEARN from the *Denver Medical Times* that a physician, Dr. H. Fremey, has been sent by the French government to Colorado to study its climate.

REGULATING VETERINARY MEDICINE IN PENNSYLVANIA.—A committee of well-known practitioners of veterinary medicine in Philadelphia and other parts of Pennsylvania has recently drawn up an address to the Legislature, recommending to its attention the importance of adopting some measure to regulate the practice of veterinary medicine in the State. The address recites the value of the cattle in Pennsylvania, which is put at about one hundred and twenty-five million dollars. In addition to this, the committee dwells upon the danger of communication of tuberculosis from animals to man.—*Medical and Surgical Reporter.*

THE ANNUAL ADDRESS OF THE BELLEVUE HOSPITAL ALUMNI ASSOCIATION will be delivered this year by Professor William Osler, of Johns Hopkins University.

THE LIGHTS AND SHADOWS of medical education in the State of Colorado are being shown up in the official organ of the County and Town of Boulder, where is located the Medical Department of the University of Colorado. One of the professors in this institution, a Dr. Mayfield, has been asked to resign because he secured too frequent and

favorable mention of his cases in the local papers, and in general disseminated too actively the knowledge of his peculiar skill and usefulness by means of the press. The paper which contains an advertisement of the ex-professor's infirmary for chronic diseases contains a counter charge by him against the Faculty of the Medical School. These gentlemen, says Dr. Mayfield, have been publicly recommending an indecent book called "Maiden Hood and Woman Hood." From the typography one would think that this was only some innocent work on millinery; but the context shows it to be physiological.

THE LANCET MEDICAL FUND.—The proprietors of *The Lancet* propose to set apart annually the sum of at least $1,500 to be used for the pecuniary assistance in emergencies of medical men or of their widows, orphans, or dependent relatives.

CALOMEL AS A DIURETIC acts best, according to Dr. Stritzig, in cardiac dropsy.

A NEW INSANE ASYLUM.—The Vermont Legislature has appropriated $100,000 for the building of a new Insane Asylum.

DR. E. B. BRANDT, of Mechanicsburg, Penn., died on January 19th. He graduated at Jefferson College in Philadelphia in 1855, and was sixty years of age.

VASSAR HOSPITAL.—The management of this hospital, at Poughkeepsie, N. Y., is severely critisised by Dr. Porteous of that place. "There are," he says, "never more than eight patients in the institution, which has a staff of thirteen physicians and surgeons." He adds: "It is easier to get a patient into a hospital in New York City, where he or she does not belong, than it is to get anybody in at Vassar Hospital." We trust that this statement is made under a misapprehension. There is no better equipped hospital of its size in the State and none better fitted for its special work.

THE BUM'S MIXTURE (*Mistura Errabundi*) has long been a favorite remedy at Bellevue Hospital for cases of recurrent indolence, and the undue attachment of healthful bodies to hospital wards. The New York Hospital claims to have something superior in the same line, which is called "The Undertaker's Revenge," and is an appetizing combination of copaiva, castor, ether, quinine, etc.

THE DENGUE NOT AT ST. AUGUSTINE.—Dr. A. Anderson, of St. Augustine, Fla., writes that the report that dengue prevails in St. Augustine is not true. A few cases were observed in September and October, but there are none now.

MR. JOHN BRIGHT, whose illness has been so earnestly watched and widely heralded, is in fact suffering from Bright's disease, complicated with diabetes. He is being attended by a homœopathic physician, who, with the help of good nursing, is steering him along between the Scylla of glycosuria and the Charybdis of albuminuria.

SAINT BARTHOLOMEW'S HOSPITAL AND DISPENSARY.—This institution was incorporated in December, 1888, for the free treatment of the diseases of the genito-urinary organs, both venereal and non-venereal, and of the skin. The President of the Board of Governors is Dr. George A. Peters. The members of the Consulting Staff are Drs. George H. Fox, Charles MacBurney, and George A. Peters. The Visiting Surgeons on the Genito-urinary service are Drs. C. T. Adams, E. B. Bronson, F. T. Brown, W. B. Clark, J. A. Fordyce, and F. J. Leviseur. The Dermatologists are Drs. G. T. Jackson, P. A. Morrow, and C. C. Ransom. These names are well known to the medical public, and of themselves are sufficient to give character to the hospital. An excellent site has been found at 84 Carmine Street, and the dispensary will open for patients about the middle of January. The idea of a hospital of this sort is not new, but until now it has lacked encouragement from the public. While there is a great deal of medical advice given gratis to the people of this city, the large class of venereal diseases is recognized in but few of the dispensaries, and only in Charity Hospital is there any provision for their special care.

DR. FRANK P. FOSTER.—We are most happy to learn that our esteemed colleague, Dr. Frank P. Foster, editor of *The New York Medical Journal*, is convalescing from his recent severe and critical illness. His numerous friends will rejoice with his family and unite in wishing him a speedy return to his former health and usefulness.

THE NEXT MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The meeting of the State Medical Society will be held February 5th, 6th, and 7th. It is the intention of the majority of the delegation to go to Albany on February 4th, at 3.30 P.M. Certificates will be sent to members and delegates of the New York State Medical Society, which can be exchanged for tickets at reduced rates, at the ticket office of the Hudson River Railroad, Grand Central Depot. The commutation rate to Albany and return, is $4.65 cents, against $6.20 cents, the regular fare. The delegation will have a drawing-room car for their exclusive use. Those who desire seats reserved should notify the Secretary, Dr. Clarence C. Rice, 115 East Eighteenth Street, at once.

MONEY FOR STATE SANITATIONS.—Illinois stands third in the list of States, when arranged in the order of the amounts appropriated for sanitary matters. Massachusetts leads with over $100,000, Texas following with $60,000, and Illinois coming to the front with a total of $49,000, including the emergency fund.—*Sanitary News.*

DRAKE'S PHARMACEUTICAL JOKE.—It is said that Drake, when the ships of the Armada turned their tails, sent to Elizabeth the word "Cantharides"—that is, "The Spanish fly."

SIR WILLIAM GULL has had another slight apopletic stroke, from which he is recovering.

AN OLD REMEDY DOOMED.—Spirits of nitrous ether is a drug that has become a household remedy; and as it is harmless always and somewhat helpful at times, its domestication in the family medicine-chest meets approval. The drug is, however, uncertain in composition and effect, its virtues depending, it is believed, chiefly upon its nitrite. A pure solution of ethyl nitrite has been found by Professor Leech, of London, to have exactly the same effect as the spirits when given in equivalent doses. Professor Leech is, therefore, of opinion that since a fairly stable solution of pure ethyl nitrite is now available, the formula for its preparation should be included in the "Pharmacopœia," and that the time-honored spiritus ætheris nitrosi should disappear from the list of official remedies.

Dr. Charles Osterlin, the discoverer of natural gas in Findlay, O., and a well-known physician, died there on January 18th from paralysis, aged eighty-two years.

The Philadelphia Polyclinic has established a special course in ophthalmology, to extend over three months, and embrace systematic didactic instruction and quizzing, with three hours of clinical work daily.

An Enemy of White Bread.—Mr. T. R. Allinson, L.R.C.P., has been living for a month on whole meal and distilled water, his purpose being to show that whole meal is vastly superior to white flour, which latter, he thinks, is almost as great a curse to the country as the liquor traffic. Mr. Allinson should now live for a month on white flour and distilled water; and let us know how he comes out.

A Medical License Law in Pennsylvania.—A bill has been introduced into the Pennsylvania Legislature, which provides for the appointment by the Governor of a State Board of Medical Examiners and Licensers, composed of nine members, from lists of names submitted by the incorporated State Medical Societies of this Commonwealth. The board is to examine all applicants for license to practise medicine or surgery.

A German Hospital for Brooklyn.—The German societies of Brooklyn, N. Y., interested in the establishment of a German hospital, have appropriated about ten thousand dollars from the regular society fund to the purchase of a hospital site in the Eighteenth Ward, near the routes of the Brooklyn Elevated and other city railroads. The twenty-seven parcels of land bought aggregate 50,000 feet or more.

"Protection for American Physicians."—*The Philadelphia Press*, commenting upon our editorial "Protection for American Physicians," adds some criticisms with which we heartily agree. The *Press* says: "It is not disputed that the ranks of physicians in this country are over-crowded. If, however, doctors need to be protected from incompetent Germans they need quite as much to be protected from incompetent Americans, who are turned out of the regular medical colleges by the wholesale, and are authorized by their diplomas to practise medicine with often an entirely inadequate preparation for their work. One diploma mill, we have in mind, graduates its young men after two terms, or a total attendance of six months. Competent doctors may or may not think they require protection from this class of practitioners, but it is certain that the public do. It matters not whether the physician comes from Germany or from Kentucky, the fact that he holds a diploma from some alleged medical college ought not of itself without further proof of fitness entitle him to practise his probable ignorance upon a suffering and defenceless humanity."

Medical Department of the University of Pennsylvania.—Dr. John Ashhurst, Jr., formerly Professor of Clinical Surgery, has been elected to the chair of General Surgery, vacated by the resignation of Dr. Agnew, and Dr. James Tyson, formerly Professor of Morbid Anatomy and General Pathology, has been appointed to the chair of Clinical Medicine, made vacant by the resignation of Dr. Osler. The title of Emeritus Professor of Surgery and Clinical Surgery was conferred on Dr. Agnew. It is reported that Dr. J. William White will be made Professor of Clinical Surgery, and Dr. John Guiteras Professor of General Pathology.

The Chicago Medical Society has completely exonerated Dr. Andrew J. Coey from the charge of willingness to produce abortion made against him by the Chicago *Times*.

The Royal College of Surgeons recently passed the following resolution by a vote of twenty-one to two: "The attention of the Council of the Royal College of Surgeons of England has been called to a volume published by Sir Morell Mackenzie, which bears the title, 'The Fatal Illness of Frederick the Noble,' and the Council consider it to be their duty to express their deep regret that any member of the College should have allowed himself to publish in such a manner the charges that are therein made against distinguished surgeons who were his coleagues in the case. The Council have not sufficient means of forming a conclusive judgment on the facts which are in dispute, but in their opinion no provocation, such as Sir Morell Mackenzie alleges, can justify this publication or the language employed in it."

The Cigarette Eye.—A New York oculist claims to have discovered a disease of the eye characterized by a dimness and a "film-like gathering" over the eye, which he traces directly to cigarette smoking. He calls it the "cigarette eye."—*Maryland Medical Journal.*

The Middleton Goldsmith Lecture for 1889 will be delivered before the New York Pathological Society, in the hall of the Academy of Medicine, on February 16th, at 8:30 P.M., by Reginald H. Fitz, M.D., Shattuck Professor of Pathology in the Harvard Medical School, Boston. The subject of the lecture will be "Acute Pancreatitis, with an Especial Consideration of Pancreatic Hemorrhage, Hemorrhagic Pancreatitis, and Subperitoneal Fat Necrosis."

Death of Passed Assistant Surgeon Wilson, United States Navy.—Passed Assistant Surgeon W. G. G. Wilson was found dead in his bed on the Receiving Ship St. Louis, at the League Island Navy Yard, January 23d. He was a native of Maryland, and thirty-five years of age. He was made Assistant Surgeon on December 1, 1876, and was promoted to his present place on July 6, 1880. Dr. Wilson's body was found by a servant who went to wake him. He had only been at League Island three weeks, having been transferred from Mare Island Navy Yard. For over a week past he has suffered from insomnia, and has been in the habit of taking small doses of bromide of potassium to induce sleep. On Tuesday evening he procured a bottle of chloral containing two hundred and fifty grains from the ship's storeroom, and when discovered Wednerday morning in his stateroom the vial contained about eighty-five grains of the drug.

Death of an Old Physician.—Dr. Amos Walker, the oldest physician in Pennsylvania, died in Bucks County on Monday, aged ninety-six. His ancestor in this country, John Paxton, the famous Quaker, settled in 1682 near the spot where Dr. Walker died. The deceased man was fifty two years of age when he graduated, in 1846, from the University of Pennsylvania, he having followed farming in Bucks County until that time. He was a cousin of General Winfield Scott, and of the Hon. Robert J. Walker.

Reviews and Notices of Books.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSOURI, AT ITS THIRTY-FIRST ANNUAL SESSION, HELD AT KANSAS CITY, MO., APRIL 17, 1888.

THE volume before us is a valuable contribution to current medical literature, and contains interesting papers on several special subjects.

AN ILLUSTRATED ENCYCLOPÆDIC MEDICAL DICTIONARY: Being a Dictionary of the Technical Terms used by writers on Medicine and the Collateral Sciences, in the Latin, English, French, and German Languages. By FRANK P. FOSTER, M.D., Editor of the New York *Medical Journal*, with the collaboration of William C. Ayres, M.D., New Orleans; Edward B. Bronson, M.D., New York; Charles Stedman Bull, M.D., New York; Henry C. Coe, M.D, M.R.C.S., L.R.C.P., New York; Andrew F. Currier, M.D., New York; Alexander Duane, M.D., New York; Simon H. Gage, Ithaca, N. Y.; Henry J. Garrigues, M.D., New York; Charles B. Kelsey, M.D., New York; Russel H. Nevins, M.D., New York; Burt G. Wilder, M.D., Ithaca, N. Y. Vol. I. With Illustrations. New York: D. Appleton & Co. 1888.

READERS of medical literature have for a long time been painfully alive to the need of a good dictionary. By this we mean not merely one in which the meaning of the more commonly employed terms may be found, but one in which all the words, common and uncommon, are defined, and to which the reader can turn, with every confidence, for the correct pronunciation and etymology of the medical terms in general or occasional use. This want has now been filled, and filled in a manner that defies all criticism, by the work before us. Size is not greatness, but in a work like this, in which every effort has been made to economize space, the size is at least an indication of completeness; and when we find that the first volume comprises seven hundred and fifty-two pages, yet carries the vocabulary from A to Cacos only, some idea may be formed of the comprehensiveness of the work. The pronunciation of each word is clearly indicated by means of a simple and easily understood scheme printed at the foot of each page. The pronunciation of the Latin terms is given according to both the English and the Roman method. The author has, we think, done wisely in introducing the latter method, for most college-students at the present day are learning to pronounce in that way, and it will not be many years, we hope, before the barbarous and absurd English method will be no longer heard in medical schools or societies.

The vocabulary embraces not only all the strictly medical terms now in use, and that have ever been current in the medical literature of English-speaking countries, but also all the technical terms used by writers on physics, botany, zoölogy, and chemistry which have any medical bearing. The names of chemical substances are inserted very liberally, in view of the fact that materia medica is constantly receiving additions of substances, such as acetanilide, which were before known only to chemists. As the title indicates, this is a French and German, as well as an English, dictionary. Anyone who has occasion to read works in either of these languages, especially the German, will appreciate the value of this. Illustrations have been introduced quite freely in order to render more clear the definition of the words, but they have been used with rare judgment, and add greatly to the value of the work. They refer chiefly to anatomical and botanical subjects, and really economize space by doing away with the necessity of lengthy descriptions, showing at a glance what would take many lines of text to explain clearly.

A work of this kind cannot be reviewed, it can only be criticised. But criticism, as generally understood, implies unfavorable criticism, and this cannot be applied to Dr. Foster's dictionary. It is a work that stands unrivalled in any country, and America may well be proud of it. For comprehensiveness and scientific accuracy it can be compared only to "Murray's Dictionary of the English Language" now in course of publication, and we doubt whether even that stupendous work can equal the one before us in its own peculiar sphere. The author is to be congratulated upon having so nearly completed a work which will be the standard authority in medical terminology for many years to come.

THE EXTRA PHARMACOPŒIA, with the Additions introduced into the British Pharmacopœia, 1885. By WILLIAM MARTINDALE, F.C.S., late Examiner of the Pharmaceutical Society, and late Teacher of Pharmacy and Demonstrator of Materia Medica at University College. MEDICAL REFERENCES, and a Therapeutic Index of Diseases and Symptoms, by W. WYNN WESTCOTT, M.B. Lond., Deputy Coroner for Central Middlesex. Fifth edition. London: H. K. Lewis. 1888.

THE fifth edition of this unpretentious, but very useful, therapeutic hand-book contains a number of new preparations that have been introduced into English practice during the three years that have elapsed since the publication of the fourth edition. The book is neatly printed and of convenient size, and the arrangement of the matter is such as to greatly facilitate ready reference. It ought to be very useful to busy men who desire to keep well informed concerning the new therapeutic remedies, many of which have already earned for themselves a permanent place in the Pharmacopœia.

NATURE'S HYGIENE: A Systematic Manual of Natural Hygiene, containing a Detailed Account of the Chemistry and Hygiene of Eucalyptus, Pine, and Camphor Forests, and Industries connected therewith. By C. T. KINGZETT, F.I.C., F.C.S., Past Vice-President Society of Public Analysts; Past Member of Council Institute of Chemistry of Great Britain and Ireland; Hon. Member Société Française d'Hygiène; Author of "The History, Products, and Processes of the Alkali Trade;" and "Animal Chemistry; or, The Relations of Chemistry to Physiology and Pathology." Third edition. London: Baillière, Tindall & Cox. 1888.

IN this book the author treats, in a popular way, of the sanitary properties of the eucalyptus and pine trees, and seeks to show that their favorable influence is due to a process of slow oxidation of the impurities and morbific agents present in the atmosphere. The work is very readable, for the author writes in a pleasant style, and the chapters are so arranged that each one forms a complete essay in itself, so that they need not be read in order, but can be picked out and studied here and there at the reader's convenience or desire. The book contains also considerable information on subjects not strictly scientific, as, for example, the collection of turpentine from the pine trees in our Southern forests.

THE PASSAGE OF AIR AND FÆCES FROM THE URETHRA. By HARRISON CRIPPS, F.R.C.S., Assistant Surgeon to St. Bartholomew's Hospital; late Surgeon to the Great Northern Hospital; author of "Diseases of the Rectum and Anus," and Jacksonian Prize Essay on "Rectal Cancer." London: J. & A. Churchill. 1888.

THIS monograph was written to record the results of the author's investigation into the cause of this rare condition, which he was led to make after meeting with two cases in his own practice. He had supposed that the phenomenon was indicative of malignant diseases, but his studies led him to the opposite conclusion. He has collected the records of sixty-three cases, only nine of which were cancerous. Two were traumatic, forty-five were due to abscess, and in seven the cause was not stated. As regards treatment, Mr. Cripps advocates colotomy as offering the best chance for the healing of the fistulous tract.

ON THE HISTORY, NATURE, AND TREATMENT OF SYPHILIS. By J. L. MILTON, Senior Surgeon to St. John's Hospital for Diseases of the Skin. London: Henry Renshaw. 1887.

THIS is a very exhaustive treatise on syphilis, written by a man who has decided views on the subject, but who is not afraid to set forth clearly and fully the opinions of others at variance with his own. The author writes pleasantly and forcibly, and a perusal of the work will repay the reader, even though he may not find himself in the end converted by the arguments here set forth.

CONTRIBUTIONS TO CLINICAL AND PRACTICAL MEDICINE. By A. T. H. WATERS, M.D., Fellow of the Royal College of Physicians of London; Consulting Physician to the Liverpool Royal Infirmary; late Professor of Medicine in University College, Liverpool, and formerly Physician to the Liverpool Northern Hospital. London: J. & A. Churchill. 1887.

THIS is a collection of essays and lectures on subjects relating to pulmonary and pleural affections. In Chapter I. the question of temperature in phthisis and some other diseases is discussed, and the importance of thermometric observations in these affections insisted upon. Other chapters treat of pneumonia, cancer of the lungs, diseases of the bronchial tubes, tapping for pleuritic effusions, Alpine winter climates, etc. The book is readable, and contains many practical points that are worthy of thought and study.

LES STATIONS D'EAUX MINÉRALES DU CENTRE DE LA FRANCE. La Caravane Hydrologique de Septembre 1887. Par MM. DR. P. DE PIETRA SANTA et A. JOLTRAIN, Président et Secrétaire de l'Excursion. Paris: Georges Carré. 1888.

THIS is an account of an excursion made in September, 1887, to several of the mineral springs of Central France. The first part treats in general of the therapeutic value of climatology and hydrotherapy; the second part contains an account of the journey; and the third part consists of the lectures delivered at each stopping-place before the physicians taking part in the excursion. The book contains much valuable information concerning many of the most important of the French mineral springs, including La Bourboule, Royat, Saint Honoré, and Vichy.

BULLETINS DE LA SOCIÉTÉ ANATOMIQUE DE PARIS. LXIIe Année (1887), 5me Série, Tome I. Rédigés par MM. DARIER et MARFAN, Secrétaires. Paris: G. Steinheil. 1887.

THIS volume comprises the transactions of the Anatomical Society of Paris for the year 1887. It contains a number of interesting reports on the most varied topics relating to pathology and human anatomy, many of which are illustrated. A fairly complete index adds to the value of the book as a work of reference.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR OF THE REBELLION. Part III., vol. i. Medical History. Prepared under the direction of the Surgeon-General United States Army, by CHARLES SMART, Major and Surgeon, U.S.A. Washington: Government Printing Office.

THE third part of the series of Medical History of the War of the Rebellion fully sustains the reputation of the preceding volumes; in fact, considering the subjects treated it excels either of the other two in practical value. The subject of camp fevers forms the bulk of the present volume, and the treatment of this class of diseases in all their phases is the most exhaustive of its kind in any language. It is impossible to indicate, even in outline, the immense amount of material which has been worked over and arranged by the painstaking and indefatigable editor. The volume, ponderous as it is, is so full of valuable information, founded on accurate and exhaustive study, that it is impossible to do more than refer to the fact as indicating its great value to every army surgeon and every general practitioner throughout the land. The admirable illustrations are in themselves works of art aside from the accurate representations of pathological conditions. This was what might have been expected, considering the fact that they were prepared by the late lamented Dr. Woodward.

TRAITÉ PRATIQUE ET CLINIQUE D'HYDROTHÉRAPIE. Par E. DUVAL, Médecin en Chef et Fondateur de l'Institut Hydrothérapique de l'Arc-de-Triomphe; Ex-Président de la Société de Thérapeutique Expérimentale de France; Officier d'Académie, etc. Avec Figures. Préface par M. le Professeur Peter. Paris: J. B. Baillière et Fils. 1888.

THIS is a very practical treatise on the subject of hydrotherapy, describing in detail the modes of application and the appliances used, as well as the indications for the employment of hydrotherapy. The author, who is an enthusiast on the subject, seeks to raise this branch of therapeutics to the level of an exact science, and shows that when employed in conjunction with other remedies it is capable of producing excellent results in the treatment of many diseases.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U.S.A. Authors and Subjects. Vol. ix. Medicine–Nywelt. Washington: Government Printing Office. 1888.

THIS volume includes 13,151 author titles, and represents 6,834 volumes, 12,818 pamphlets, and 29,120 titles of articles in periodicals. It has been prepared under the direction of Dr. John S. Billings, as have been the former volumes.

PRESCRIPTION WRITING. Designed for the Use of Medical Students who have never studied Latin. By FREDERICK HENRY GERRISH, A.M., M.D., Professor of Anatomy, and formerly Professor of Materia Medica and Therapeutics, in Bowdoin College; Surgeon to the Maine General Hospital, President of the Maine State Board of Health, President of the American Academy of Medicine, etc. Seventh and revised edition. Portland, Me.: Loring, Short & Harmon. 1888.

THIS is a well-arranged little book, and the rules of the Latin grammar, as far as they are needed in prescription writing, are clearly stated. It is one of the best books on prescription writing that we have seen, and the fact that it is very short is not the least of its merits, for we have some doubts concerning the practical utility of works of this sort that are intended to supply certain deficiencies, which of themselves should deter one from entering upon a life of continuous scientific investigation such as is, or should be, a physician's.

CHEMICAL EXPERIMENTS FOR MEDICAL STUDENTS; ARRANGED AFTER BEILSTEIN. By W. S. CHRISTOPHER, M.D., Demonstrator of Chemistry, Medical College of Ohio, Cincinnati. Cincinnati: Robert Clarke & Co. 1888.

AT the present day, when there is such an awakening to the necessity of a more thorough medical education, it is not unreasonable to hope that all our colleges will soon see the need of giving students some practical instruction in chemistry. And when this time comes we know of no work that will be found better adapted as a guide in such study than this. The experiments are simple, yet ample, to initiate the student into the principles of chemical analysis, and are arranged in a progressive series, so that the novice will not be discouraged by meeting with difficulties at the outset. A number of blank pages are bound up with the book to serve for notes and additional experiments.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 17, 1889.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT introduced as guests Dr. Paul Gibier, of Paris, and Dr. Louis Bauer, of St. Louis.

YELLOW FEVER; EXPERIMENTAL RESEARCHES INSTITUTED IN FLORIDA UNDER DIRECTION OF THE FRENCH REPUBLIC.

DR. PAUL GIBIER read the paper under a somewhat different title from that on the cards of announcement: "Yellow fever; experimental researches on its etiology."

At the beginning of 1888 he had read a paper containing the results of researches he had undertaken on yellow fever, started in November, 1887. Since that time he had spoken of his work on the subject before the Academy of Medicine in Paris. In September, 1888, in consequence of these studies, the French government, which four times before had honored him with its confidence for other investigations, gave him the mission to go to Florida and study yellow fever, which was prevailing there at that time.

When he arrived at Jacksonville the epidemic had begun to decline, but he was able to study several cases of undoubted yellow fever. Before reciting those cases the author considered the question, which was one of doubt in the minds of some physicians, whether this was or was not really an epidemic of yellow fever, and the conclusion which he arrived at was, that while a number of deaths were due to the fevers prevalent in the country, and that such fevers caused some cases of yellow fever to run a modified course, yet the epidemic was one of genuine yellow fever. He saw some cases which were absolutely as characteristic, judged by the symptoms and pathological lesions, as any he had seen at Havana or elsewhere. He had opportunity to make bacteriological observations in comparatively few cases, but these were confirmatory to a degree of the more numerous observations made in Havana, in 1888.

The substances which had been planted in cultures had been taken with every precaution. While it was not impossible that the micro-organisms which developed in the fluids experimented upon during the culture process were introduced in the necessary manipulations, yet, this uncertainty, he thought, did not exist in the case of the solid media. While he admitted, as he had done in preceding publications, the introduction of the micro-organisms into the hollow viscera as possible, owing to alterations in the mucous membrane, yet this possibility seemed excluded in the case of the liver, spleen, and kidneys. Dr. Gibier gave the results of cultures made in about six cases at Jacksonville; in one case, however, the disease was not yellow fever. The fifth case was that of a light mulatto, aged thirty-five, who died after four days' illness, with undoubted symptoms and lesions of yellow fever. The liver was "nutmeg," the kidneys congested, the stomach and bowels contained a large amount of black liquid, the contents of the stomach being acid, of the small intestine decidedly alkaline, of the large intestine neutral. Cultures were made of the blood, kidneys, liver, spleen, and intestinal contents. The blood was sterile. The kidneys, spleen, and liver contained some microbes of decomposition, and it was to be remarked that the autopsy was made eight hours after death, the temperature was high, and the conditions were very favorable for the early development of the microbes of decomposition. The interest in the case centred in the fact that the intestinal fluids contained the microbe which he had isolated in Havana, and believed to be the origin of yellow fever.

In this, the fifth, case alone did he find the particular bacillus which was present in certain cases examined at Havana. It was seen only in the contents of the intestine; the case had run rather a rapid course to a fatal termination on the fourth day. The black liquid in the intestines was plentiful, and of alkaline reaction (fluids of acid reaction destroyed this microbe). It was noticeable that the liquid cultures of this microbe resembled in character the black vomit; he could not assert, however, that this fact possessed any significance. The blood, liver, kidneys, and spleen had been found constantly free from the microbe.

The theory which Dr. Gibier had supported was, that yellow fever was an intestinal affection, and if that were true, it should be treated from the beginning by remedies directed to the intestinal tract, as by the use of such disinfectants as bichloride of mercury, naphthalin, and tannic acid. There were two objections to this theory which he would answer: 1, If yellow fever was an intestinal disease due to a micro-organism, why was this not found in all cases after death? 2, If this cause were admitted, how could one explain the albuminuria present?

In answer to the first question, he stated that after a micro-organism had saturated a culture-medium its growth stopped. And, if then another microbe were introduced it would replace the former. So it might be in the fluids of the intestine in yellow fever. As soon as he should have opportunity, it was his intention to examine the dejecta of patients, from the first day of the disease until the last, for proof of this view. He would not be surprised to find his microbe in some cases only during the first days of the disease. The alterations in the other organs during the course of the disease might be accounted for by the ptomaines generated by the microbe which entered and poisoned the blood. The poisons seemed to be especially plentiful in the radicles of the vena porta. As to the presence of albuminuria, he remarked that it was not unusual for it to be present in other affections, as typhoid fever, where the original lesion was in some other organ.

DR. STERNBERG had found the microbe described by Gibier in three cases, in which he had looked for it. It was Dr. Gibier's opinion that if yellow fever was a bacterial disease, it would not be impossible to confine it to the inhabitants of countries exposed to the epidemic.

DR. L. B. BULKLEY then read a paper (which will appear in THE MEDICAL RECORD hereafter), entitled

UNUSUAL METHODS OF ACQUIRING SYPHILIS, WITH REPORTS OF CASES.

DR. SAMUEL T. HUBBARD inquired of Dr. Bulkley, whether in his opinion syphilis could be conveyed to the nursing child through the milk. He was prompted to ask the question from having seen a case in which the infant acquired syphilis through the nurse, the latter, however, having no lesion at the time the infant contracted the disease.

DR. BULKLEY expressed the belief that the milk could not transmit syphilis.

THE PRESIDENT suggested, in explanation of Dr. Hubbard's case, that milk was not always the same. That from a healthy woman was a secretion composed mostly of transformed epithelium. Such milk would not transmit syphilis. When, however, the woman's health deteriorated, as in states of anæmia, the milk became largely a simple transudation from the blood, and was composed chiefly of blood-serum and its contents. Such milk might transmit syphilis.

SECTION IN SURGERY.

Stated Meeting, January 14, 1889.

ROBERT F. WEIR, M.D., CHAIRMAN.

ELECTION OF OFFICERS.

DR. ROBERT ABBE was elected chairman of the section for the ensuing year, and Dr. Charles A. Powers, secretary.

EXSTROPHY OF THE BLADDER; WOOD'S OPERATION.

DR. WILLIAM T. BULL presented a boy, about nine years of age, illustrating the results of Wood's operation

for extroversion of the bladder. The condition was a somewhat rare one, consisting in a congenital malformation, with the mucous membrane of the bladder exposed in the hypogastric region and the ureters opening externally. He first tried to destroy the mucous membrane of the bladder, and sew the ureters to the glans penis, but failed. Wood's operation was performed in August, and consisted in making three flaps, the central one being turned with the skin down, and the other two united in the middle line with their raw surface pointing downward. The raw surface, left from dissecting up the flaps, healed within eight weeks. The operation proved a success, resulting in a cutaneous surface taking the place of the mucous surface which previously had given rise to much discomfort from irritation. Of course, the capacity of the bladder as a reservoir had not been increased. He thought the case was worthy of presentation, as showing good results from an operation which was not frequently performed. The boy had been wearing an apparatus for collecting the urine, and although it had answered the purpose well, it had to be laid aside on account of the irritation which it had caused by pressure.

THE CHAIRMAN had seen four cases of exstrophy of the bladder, but had been in doubt whether he could benefit his patients much by any of the procedures which had been suggested or tried. Some years ago, he saw a patient of Dr. Van Buren wearing a rubber cover and reservoir, which made him quite free from the ill effects of continual drain of urine from the mouths of the ureters.

DR. L. B. BANGS had seen two or three cases of exstrophy of the bladder, but had not thought it advisable to operate.

DR. DE GARMO presented photographs of a case which came under his care about three years ago, that of a married woman who had borne one child. The labor was normal, but subsequently complete prolapsus of the uterus occurred. There was complete separation of the symphisis pubis. She was a marked sufferer from the constant irritation of the prolapsed uterus and exposed mucous surface of the bladder. Dr. De Garmo replaced and supported the uterus, and also protected the exposed bladder by an apparatus, consisting of a spring passed around the waist, a rubber pad between the thighs, a cup pessary for the uterus, and conducting the urine to a urinal strapped to the leg. The relief was very marked.

DR. J. B. BISSELL then presented a child with

CONGENITAL DEFORMITY OF BOTH KNEES,

which was first brought to Dr. Gibney's clinic in December, 1887, when seven weeks of age. The child was born at full term, normal labor, but breech presentation. When first seen, both tibiæ were luxated forward, there was considerable spasm in the great extensors of the thigh, the condyles of the femur projected into the popliteal space. The patellæ were small. The spasm of the quadratus femoris prevented any flexion of the knee, and held the leg extended fifteen degrees beyond the straight line. There were some deep creases about the joint. The ligaments were all relaxed except the ligamentum patellæ. Marked flexion at the knee was impossible, even under chloroform. At present the child could flex the legs without difficulty, but when it attempted to walk the knee refused support. The left knee showed a worse condition than the right.

UNUSUAL CONGENITAL SUBLUXATION OF THE KNEE-JOINT.

DR. L. H. SAYRE presented a baby whose left tibia, at birth, was luxated forward so that the toe rested upon the abdomen, and the leg projected forward, forming an angle of forty-five degrees with the thigh. There was no muscular spasm. By the aid of the hand the leg could be brought down to the straight line. The condyles of the femur were plainly felt in the popliteal space. The other leg was normal. Both were of about the same size and length. The deformity was gradually being overcome by a retention apparatus.

DR. V. P. GIBNEY read the description of a similar case by Dr. Taylor, of Texas. The boy, of about twelve, was then only able to balance himself on his legs, but in going about supported himself by both hands and feet. The legs were hyperextended upon the thighs, forming an angle on the left side of 120°, and on the right of 100°. They could by force be brought to a straight line. Motion in the knee was smooth and painless. The patellæ were small. The muscles of the leg were atrophied; there was some talipes equinus in the right foot.

Dr. Gibney remarked that he once had a boy under observation in whom he thought there was complete absence of the patella, but a rudimentary one was found later.

DR. WIENER presented plaster casts in two cases of deformity at the knee, children of the same parents. Immediately after birth both legs were extended upon the thighs nearly at a right angle. The labors had been normal. The patellæ were small.

DR. KETCH mentioned a case in which the subluxation at the knee had been mistaken for exaggerated knock-knee. Closer examination showed the dislocation of the femur backward into the popliteal space, and marked hyperextension of the leg. The child was then aged six years, but the mother had noticed the deformity when it first attempted to walk. There was marked relaxation of the ligaments. The joint could be easily manipulated except laterally.

DR. TAYLOR said he presented at the Northwestern Medical and Surgical Society almost a duplicate of the case presented by Dr. Bissell. The child was one of twins, was a breech presentation, and the thighs were flexed upon the abdomen and the legs hyperextended upon the thighs, and remained so for some time after delivery. The patellæ could not be felt. There had been marked mobility laterally at the knees, but the hyperextension and lateral mobility had been largely overcome by retaining apparatus. In other respects the child's health was good.

DR. A. JACOBI remarked that he had seen absence of the patella in but one case. It was supposed to have been found in another, but later a very small one was felt. He suggested that lack of sufficient liquor amnii, causing a cramped position of the child, might be the cause in some instances of hyperextension or hyperflexion of the limbs. It was not uncommon to see babies with marked flexion of the limbs for a long time after birth, and the same cause operating in a more marked degree might give rise to the malformation seen in the cases related this evening. When floating about freely during utero-gestation there was opportunity for the muscles and other tissues to obtain their normal development. He had observed in Dr. Bissell's case absence of the reflexes in the right lower extremity, which might point to a spinal affection.

CERVICO-THORACIC FISTULA.

DR. F. HÜBER presented the patient, a boy of six years. His trouble dated back to the latter part of July, 1887, when there was evidence of phlegmonous erysipelas in the right side of the neck. Symptoms pointing to an abscess developed, which was evacuated through an incision at the side of the sterno-cleido-mastoid. The patient improved, but afterward signs pointed to fluid in the left pleural cavity. An opening was made below the axilla and pus escaped. Injections made at this opening escaped through the one above the clavicle, and when made at the opening above, escaped through the incision into the pleural cavity. The temperature still remained up, the superior wound was enlarged, the finger introduced behind the sternum, and an abscess opened in the antero-mediastinal space. Eleven months later two ribs were resected posteriorly. This wound healed within three weeks. A few days afterward a prominence presented in the left cervical region. This was opened, and a large amount of pus escaped. A uterine sound was then passed

through from the cervical opening to the infra-axillary opening, and a strand of iodoform gauze was left in three weeks. A silk thread, passing from the upper wound down through the lower, was now being worn to prevent the former from closing. By moving this thread up and down a large amount of fluid was permitted to escape in November last. When the child was presented, the discharge was very slight, yet it was probable that further operative procedure would have to be resorted to. The lungs were well filled out; the general health had much improved the past year.

DR. HÜBER also presented a case of

PULMONARY ABSCESS IN A CHILD.

The boy was aged four years; was first seen by Dr. Hüber in October. He had been sick five weeks with what was called pleuro-pneumonia. During this time he presented high temperature, irregular chills, diarrhœa, and sweating—indications of a suppurative process. On the right side, anteriorly, he found flatness over the lung, with absence of vocal fremitus. On deep inspiration, there was distant bronchial breathing. His diagnosis was that of local pyæmia anteriorly. Dr. Jacobi suggested the possibility of intra-pulmonary abscess. An exploratory puncture revealed pus, but an incision on the upper border of the fourth rib into the pleural cavity failed. Further exploration, however, brought out about a drachm of pus, and a drainage-tube was introduced. Two days later about two ounces of pus were on the dressings. At present there escaped not more than two drachms in four days, and there had been general improvement. When small injections were made there was no cough; when larger ones were made spasmodic cough resulted, until what fluid had been injected into the bronchi had been expectorated. He supposed that in passing through the pleura the distance was half an inch. Some pneumonia had resulted from his punctures, but it had resolved satisfactorily.

AMPUTATION FOR CHARCOT'S JOINT DISEASE.

DR. LAYTON presented the patient, a man aged sixty, who entered Bellevue Hospital July, 1887. He had had gonorrhœa and chancroids. The last seventeen years he had had what he called chronic rheumatism, consisting of attacks of pain coming on at irregular intervals, and confined to the lower extremities. They were always relieved by counter-irritation and rest. Eight years before, he first noticed difficulty in balancing in the dark, and afterward was annoyed by tingling sensations in the feet. His nephew, a physician, diagnosticated locomotor ataxia. There was also some enlargement of the left knee. This went on enlarging, but he was able to walk without difficulty by the aid of a cane. In July, 1872, he had an attack of retention of urine. It was drawn by catheter, and since then there had been incontinence, and also slight incontinence of fæces. The day before admission to the hospital he got wet while fishing, and afterward found his left leg give way when he attempted to use it. At the hospital the left knee was found enormously distended with fluid. It disappeared under treatment, and then both femurs were found enlarged. Manipulation was not attended by pain. There was a distinctly grating sound in the knee, and the ligaments were destroyed. He remained in the hospital and enjoyed fair health. The fluid would return in the left knee from time to time, but disappeared under pressure. Finally, this treatment failed, and aspiration brought forth serum and a small amount of pus. The patient consented to amputation, and Dr. McBurney did Spence's operation. The dressing was removed at the end of the second week, when primary union was found to have taken place. Dr. Layton spoke favorably of this operation, which left the cicatrix back of the thigh, away from pressure by the artificial leg. The opposite knee was well, there were no symptoms of locomotor ataxia, and the patient was in much better condition than when he entered the hospital.

THE CHAIRMAN thought from limited experience that considerable advantage was gained in cases of this kind from excision of the knee-joint, provided amputation were not advisable or permitted.

DR. SYMES had observed that resection gave less favorable results in these cases than one would anticipate from a study of the pathological changes.

DR. L. BOLTON BANGS read a paper (see p. 85) entitled

ON SPASMODIC URETHRAL STRICTURE FROM ANAL FISSURE.

THE CHAIRMAN referred to a case of vaginismus, almost forbidding coition, which disappeared by treatment of an anal fistula.

ENLARGEMENT OF THE THYROID GLAND.

THE CHAIRMAN presented nine small tumors, separate portions of the enlarged thyroid, each of which was removed from a more or less distinct capsule. This method of removal presented certain advantages. It was important to leave a portion of the thyroid, since in Europe, where a much larger number of cases of goitre developed than here, it had been found that its entire extirpation was likely to be followed by myxœdema. It was not uncommon to find one or several cysts in the tumor.

DR. B. F. CURTIS had operated in a case which contained a cyst as large as an orange. It was "shelled out."

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 28, 1888.

W. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. RICHARD VAN SANTVOORD presented some specimens showing

PRIMARY TUBERCULOSIS OF THE GENITO-URINARY TRACT.

The patient, J. G——, had been under observation at intervals for about three and a half years, in the Randall's Island Hospital, his main trouble being supposed to be chronic diffuse nephritis. The urine was generally of low specific gravity, frequently below normal in quantity, and usually containing a moderate amount of albumin. Casts of various sorts were found from time to time. Within two years the epididymis, first of one side, and, after a short interval, of the other, became swollen, hard, and finally suppurated. A sinus also formed over the sacrum, discharging pus. The strength, meanwhile, failed gradually. For about six weeks, during the last summer, he was troubled with frequent micturition and his urine was observed to contain considerable pus. Under treatment the symptoms subsided and the cystitis was supposed to have been cured. Attention was drawn to his lungs only a few weeks before death, which occurred November 10, 1888.

The autopsy disclosed a very emaciated body, with a sinus over the sacrum leading into the right sacro-iliac synchondrosis, whose bony surfaces were rough and carious. The cartilage of the left fifth rib was softened and necrotic, and communicated with an abscess under the pectoral muscles. The pia mater was thickened, and a single small tubercle was found on the convexity of the left side of the cerebrum. The heart was pale and slightly atrophied. The lungs showed firm gray, tubercular clusters throughout, some dilatation of the bronchi, rather recent pneumonic consolidation of left lower lobe, old adhesions over right lung, and recent ones over left.

Both kidneys were invaded by tubercles, affecting most extensively the pyramidal portions, but extending also in many places through the cortex. The tubercular material was for the most part cheesy, and in places was breaking down. The portions of the kidney not invaded by tubercle showed the cortex to be considerably atrophied, the markings indistinct, and the cut surface of a mottled yellow color. The right ureter showed two tubercular masses, one-twelfth of an inch in diameter where the

ureter passed over the brim of the pelvis. In the left ureter there were two small masses near the renal pelvis. The mucous membrane of the bladder was ulcerated away for about one inch around the urethral orifice. Back of this was a second ulcer, about three-fourths of an inch in diameter, and several smaller ones were scattered over the vesical surface. The prostatic urethra was extensively infiltrated, the process extending forward into the spongy portion of the urethra. Small tubercular masses also were scattered all along the urethra, in decreasing numbers as the meatus was approached. The prostate was extensively infiltrated and cheesy. The right vesicula seminalis formed a cheesy mass about ½x¼ inch in size. The left was slightly involved in the same process. The epididymis on each side was enlarged and cheesy. The body of one testicle was invaded by more recent gray tubercle. The other was normal. The intestines showed some enlargement of the solitary follicles and old adhesions. The liver was normal in size, but universally adherent, and on both the free and the cut surfaces a few small tubercles were observed. Diffuse cirrhosis, moderate in amount, existed.

The case seemed to have been one of primary tuberculosis of the genito-urinary tract, because the lesions, particularly in the kidneys and about the neck of the bladder, were much more advanced than those in the lungs. Their extraordinary latency was very remarkable. Prior to the development of symptoms pointing to cystitis nothing was discovered in the urine to suggest anything more than chronic nephritis, although it had been frequently examined. It did not seem possible to determine which began first, the nephritis or the tubercular kidney lesion. The former was positively known to have existed for three and a half years, and probably antedated the patient's first entrance into the hospital.

There was one question, Dr. Van Santvoord said, which he would be glad if any of those present could answer for him, and that was as to the rapidity with which such a process as this could be developed. In reply to a question as to the order in which the several organs became involved, he said that the most marked lesions were found in the bladder. The epididymitis had existed for about eighteen months, and it was probable that the process had begun in this part or in the prostate gland. The pulmonary lesions were evidently less advanced than those in the genito-urinary tract.[1]

Dr. Walter Mendelson raised the question whether we were justified in unhesitatingly accepting this case as one of primary tuberculosis of the genito-urinary tract. It was true that the anatomical lesions seemed to show that the process had been longer at work in the genito-urinary tract than in the lungs; nevertheless, there was not, in his opinion, anything to show that the tubercular process might not have long been latent in the lungs, and that the genito-urinary tract had not been infected from them. This was rendered the more probable by the fact that we so often find on autopsy cheesy nodules in the lungs of persons who, during life, had given no signs of their existence. In view of the obscurity of the mode of infection in cases of genito-urinary tuberculosis, the speaker thought we should exercise the greatest caution in accepting the evidence on which the claim for primality was based in these cases.

[1] Since the above was written Dr. Van Santvoord adds the following: Ziegler (Path. Anat.) states that in the great majority of cases renal tuberculosis is embolic, but that in rare cases a tuberculosis beginning in the bladder, the prostate, the seminal canals, or the testicle may infect the kidney by way of the ureters (p. 1129, edition of 1885). On page 470 he calls attention to the identity of this mode of infection with that due to parasites, which give rise to more acute forms of disease. The predominant affection of the pyramids in the case reported, as above stated, points to infection by way of the ureters rather than by embolism. It is of course quite possible that the pulmonary tuberculosis might have been due to independent infection, especially as the patient was for a long time an inmate of a hospital ward in which there were always several cases of pulmonary tuberculosis. Kaufmann (Deutsche Chirurgie) states that tuberculosis of the urethra is very rare, and is always accompanied by extensive tuberculosis of the genito-urinary organs. It extends from the bladder and affects usually the prostatic, rarely also the membranous, urethra.

The President said that, in his opinion, the first of the genito-urinary organs to become diseased in this case was the testicle or the epididymis. It was his experience that the kidney was usually the last of all the organs to be involved.

Dr. B. Farquhar Curtis referred to Finck's studies on the subject of genito-urinary tuberculosis, the results of which seemed to prove that the prostate was infected before the kidneys.

Dr. Henry P. Loomis presented a specimen showing

PECULIAR TUMORS IN THE HEART-MUSCLE.

The heart was from a woman, twenty years of age, a prostitute, who gave the following history: She had borne three children and had had two miscarriages, the last miscarriage being about a year ago. She had always been healthy, with the exception of an attack of intermittent fever one year ago. She denied ever having had syphilis. Four days before admission to the hospital she had had a chill, followed by fever and sweating, and this was repeated twice, the last chill being on the day before admission. Since the first chill she had been troubled with dyspnœa. She had had muscæ volitantes, diplopia, frontal headache, dizziness, and swelling of the feet and legs during her pregnancies, but none in the intervals. Of late the urine had been increased in amount. On admission the physical signs were those of pneumonia. The heart-sounds were normal. The patient died on the third day after entering the hospital.

On autopsy, the entire right lung was found in the third stage of pneumonia. There were also evidences of fresh pleurisy. The liver was normal. The spleen was greatly enlarged. The kidneys presented the lesions of chronic diffuse nephritis. Pyosalpinx and purulent oöphoritis were present, and on the cervix uteri was what seemed to be a chancroid. No syphilitic lesions were found, however, in any other part of the body.

The heart was normal in size, no change was evident in the cavities or the valves, a few small atheromatous patches were noticed in the aorta, just above the valves. Two tumors the size of a French olive were embedded in the wall of the left ventricle near the auricular-ventricular septum, one an inch below the aortic valve, the other below and about an inch from the apex. The tumors were circumscribed, of a whitish-yellow color and hard consistency. A section of one of the tumors showed under the microscope that the centre was in a condition of coagulation necrosis, and that the peripheral zone was made up of round cells, between which was seen a basement substance. The round cells extended for a short distance beyond the apparent edge of the tumor in between the muscle fibres.

Dr. Prudden, who examined the section carefully, expressed the opinion that the tumor was a *gumma*. Of the tumors of the heart tubercle is the most common, while gummata are very rare. The speaker had found but a few cases mentioned in American or English literature, and these were almost always associated with gummata in other organs.

Dr. Mendelson suggested that the lesion might possibly be the result of infection from the pneumonia, and he thought it would be well to examine the specimen for pneumococci.

Dr. Loomis replied that the lesion evidently antedated the pneumonia. The process was not an active one, and there was no acute suppuration present.

Dr. Van Santvoord said that it was not uncommon to meet with cases of endocarditis caused by the pneumococcus, but in the specimen presented the process was apparently much older than the pneumonia. The gross appearance of the lesions certainly suggested a gumma.

Dr. T. H. Myers presented some specimens of

UNIVERSAL SUPPURATIVE ARTHRITIS.

Cases, he said, where two, or even several joints are involved in such a process are common enough, but in

a search through the literature of the past ten years, he had found no case of a similar *universal* joint disease.

The specimen was taken from a foundling two months old. The autopsy was made by Dr. William P. Northrup. Body well nourished; slight swelling over carpo-metacarpal joints of left hand. Brain normal, as were lungs and spleen. Liver dark, congested, slight mottlings (anæmic?), in size normal. Gall-bladder moderately distended. Kidney cortex pale, markings indistinct. Stomach empty, mucous membrane pale, amount of mucus increased. Intestines empty, mucus increased in amount, bile-stained, in stringy masses; mucous membrane pale. Bladder normal. Joints: Right sterno-costal, both temporo-maxillary, both scapulo-humeral, both elbow, both wrist, both carpo-metacarpal, both hip, both knee, both ankle, both tarso-metatarsal joints contained abundance of pus, which was also found along the tendons of all the fingers and toes. The cartilages were easily broken from the bones. The cancellous tissue of the latter was deep red, soft, and could be easily broken down with the thumb.

Unfortunately, in this case the history of the parents and the details of parturition could not be obtained, as the child was a foundling. From the fact that syphilis was suspected before death the speaker felt sure that had any of the visceral lesions of syphilis been present they would have been noted prominently, also that no suppurative condition of the umbilicus or umbilical vessels would have escaped observation. The child, when admitted to the asylum, had onychia. The left hand was reddened and swollen, as was also one foot. The baby was sore all over on handling and was thought to have syphilis. It was removed to the "Marasmus Ward," and died four days later, without presenting any other symptoms. On disarticulating the sternum and clavicle, thick pus was noticed escaping from the joint and this caused the methodical examination of the remaining joints, as detailed above, to be made.

In looking over the literature of the subject the speaker had found the case most nearly approaching this in the number of joints involved to be one reported by Dr. Huber (*Arch. f. Path. Anat.*, Berlin, 1882, lxxxviii, p. 246). At the careful autopsy made by him on this case—a premature child fourteen days old—nearly all of both the large and small joints contained laudable pus; the ligaments, bones, and cartilages were normal, the synovial membranes infected in parts only. There was œdema of the lungs; the navel and umbilical vessels were normal. There were only a few swollen glands at the lower part of the ileum. The pleura, pericardium and peritoneum were normal. He mentions, however, a bed-sore, a subcutaneous abscess on one foot, a mediastinal abscess, and a hæmatoma of the dura, with adhesions of dura and pia and a congestion and softening of the cerebral substance. The kidney contained a deposit of urates. The heart and other organs were normal. The mother had had an attack of acute articular rheumatism during confinement, followed by a relapse. As there was no history or appearance of syphilis, though a careful examination was made for this on both parents and child, nor yet of any of the exanthemata, Huber made the diagnosis of rheumatic arthritis. Dr. Myers thought this case was more like a pyæmia, either "spontaneous," or secondary to the hæmatoma or bed-sore.

Another case is reported by Lane ("Tr. Path. Soc. London," 1884–5, xxxvi., 343). Here there was purulent effusion into several joints in a child certainly syphilitic. The joints affected were the hip, the shoulder, the right knee, and both elbows. They contained an abundance of pus. The synovial membranes were very vascular. The remaining joints were normal. Lane noted no change in the ossifying layer of the cartilage, nor in the articular cartilage. The child was healthy till six weeks old, when an eruption and snuffles were noted, and emaciation became marked, the child dying twenty days later. The writer considered the acute synovitis as corresponding with the prodromal form of synovitis found in adults, which precedes the first eruption, disappearing when this has become general.

Dr. Lee (*Brit. Med. Jour.*, November 6, 1880, p. 743) reports a similar case, cured by anti-syphilitic treatment.

In considering the diagnosis in this present case, Dr. Myers said that it lay between syphilis, rheumatism, and pyæmia. In favor of the syphilitic origin was the præmortem diagnosis, and the fact that such a case is possible. On the other hand these congenital syphilitic joint-lesions are usually confined to a *very few* of the *larger* joints and are at best very rare. The epiphyseal line, or the periosteum, are the usual seats of the disease. These joints where the epiphyseal line runs within the joint limits, as the knee and elbow, are involved by preference.

Against the rheumatic origin was the extreme rarity of such cases in very young infants. Eustace Smith says ("Dis. of Children," N. Y., 1884, p. 155) the younger the child the more likely will the disease fasten upon the heart to the exclusion of the joints.

Taylor ("Dis. of Osseous System in Children," N. Y., 1875, p. 150), denies the existence of rheumatoid arthritis in infants, though recognizing it in children.

Howard ("Pepper's Sys. of Med.") regards acute articular affections in sucklings syphilitic or pyæmic as a rule, but recognizes a few authentic cases of rheumatic origin.

Widenhofer met with but one case (an infant twenty-three days old) out of a service of 70,000, and Rauchfuss in 15,000 cases found but two occurring in children at the breast (Senator, "Ziemssen's Cycl. of Pract. Med.," xvi., 17). There is usually, also, in these cases redness, swelling, and pain. The inflammation jumps from one joint to another after four or five days, and, finally, suppuration is very rare.

J. Lewis Smith, however ("Dis. of Children," N. Y., 1886, p. 399), describes briefly a form of rheumatic arthritis in young children which is not marked by redness, swelling, or much pain. The number of joints involved, however, is small. Cornil and Ranvier also ("Path. Histology," Phil., 1880, p. 228) describe cases of acute rheumatism, where the inflammation has attacked several articulations or only a single one, and the articular cavity is filled with a creamy pus, analogous to that of an abscess.

Pyæmia is the most usual cause for multiple suppurative arthritis, but though several joints are often involved the speaker did not know of another case where all were. Of this condition Billroth ("Surg. Path.," N. Y., 1883, p. 344) writes: "Purulent articular inflammation occurs in the pyæmia of the newly born. Children are even occasionally born with them, as has been witnessed by myself and others. Inflammations may develop and even run their course during fœtal life, as is shown by the cases where children are born with joints fully developed, but anchylosed."

The case seemed to belong among what Delafield and Prudden ("Handbook Path. Anat.," N. Y., 1885, p. 513) call "spontaneous pyæmia," where, without wound or fracture and without visceral infarctions, inflammation of joints and serous membranes occur with all the symptoms of pyæmia. Such cases must be very rare, as in the lungs alone metastatic abscesses are found in ninety-one per cent. of pyæmic deaths, according to Bryant's tables ("Surgery," Phil., 1881, p. 58).

A gonorrhœal origin had been suggested, the infection perhaps occurring from an ophthalmia. But there was no record of such an ophthalmia in this case, though the eyes of these children are always examined. The number of joints involved would also militate against this idea, though Fournier states that temporo-maxillary, sacro-iliac, sterno-clavicular, and intervertebral joints are affected in this disease as well as the larger joints ("Nouvel Dict. de Med. et de Chir. Prat.," t. v., p. 230).

The purulent arthritis described by Thomas Smith ("St. Bartholomew's Hospital Reports," 1874, p. 189) as originating from "subarticular abscesses," and occurring in such a large percentage of cases in infants under two

months old, was negatived here by the absence of such abscess-cavities and because this disease only involved one joint or two.

The general involvement of joints and negative history would also exclude the form of purulent arthritis in children, called by Volkman "catarrhal inflammation."

The diagnosis seemed, then, to be, by exclusion, spontaneous pyæmia.

Examination of the specimens showed smoothness of the articular surfaces; no anchylosis or periarticular thickening; no subarticular abscess-cavities; no change apparent to the eye in epiphyseal cartilage; no thickening of periosteum; no metastatic abscesses. The valves of the heart were smooth.

THE PRESIDENT remarked that cases such as this must be very rare, he himself having never seen or heard of an instance in which so many joints were involved. There were no signs of syphilis about the child, nor was there any suppuration in the umbilical vein.

In reply to the question as to whether the pus in the joints had been examined for bacteria, the President said that no examination of the kind had been made, as the case had been seen several years ago, at a time when the search for bacteria was not as eager as it was at present.

DR. JOHN S. ELY presented a specimen of

ANEURISM OF THE ASCENDING ARCH OF THE AORTA,

in which sudden death occurred without rupture of the sac (see p. 88).

DR. JOHN MESSENGER recalled a case of an enormous aneurism of the aorta, the specimen of which he had presented to the Society some twenty years ago. There was no rupture of the aneurism, but the man died in great distress. He was two months in dying, suffering all that time from extreme dyspnœa and cough. At the autopsy adhesions were found between the aneurismal sac and the sternum. The lungs were markedly compressed by the tumor.

DR. H. P. LOOMIS said that he believed that some of these cases of sudden death from aneurism could be explained by an examination of the heart-muscle. In a case of this kind which he had seen some time ago the heart seemed to be normal, but under the microscope the muscle was seen to be extensively diseased.

DR. WILLIAM P. NORTHRUP presented a specimen, showing

EXTENSIVE PULMONARY INTERLOBULAR EMPHYSEMA,

with the following history:

The patient, a female child of five months, was brought to the Out-door Department of the New York Foundling Asylum, by the nurse, who spoke only Italian. It is the habit of the Italians to return a child immediately if it becomes sick. She said the child was "little sick," and she was certain it had not whooping-cough and had never had convulsions.

The child coughed moderately, had no general depression, was well nourished, played about the room and laughed. The diagnosis of ordinary bronchitis of mild type was made, and nurse and patient sent home.

Fourteen days later patient was returned to the hospital with a temperature of 103°, with severe dyspnœa and cyanosis. It died three days later, or on the seventeenth day after the first observation was made.

Autopsy.—Body was well nourished, fat; brain normal; larynx moderately congested and dusky; mucous membrane wrinkled; aryteno-epiglottidean folds swollen and wrinkled; vocal cords normal; no ulcers in larynx; mucous membrane of epiglottis and trachea moderately congested and dusky. The mucous membrane had the appearance of being wrinkled, from post-mortem removal of a portion of the œdema and congestion.

Lungs: The left was the seat of extensive interstitial emphysema of the upper lobe. Beaded rows of air-sacs radiated from the root to the anterior margin, separating the lip of the lung so as to allow light to shine through from one lateral surface to another. One vesicle was larger than its fellows and separated the anterior upper lip of lung more than a centimetre, and bulged forward like a bladder of air under moderate pressure. At the posterior margin of the lower lobe was another air-bladder of similar size. In the posterior portion of the apex was recent pneumonia, extending about half way from apex to root, having upon the surface numerous petechiæ.

Right lung, moderate pneumonia of posterior margin from apex to base; petechiæ on pleural surface and few scattered vesicles of emphysema.

Stomach and intestines were the seat of moderate catarrh. Other organs normal.

This case had no previous history to explain the cause of the lesion. The condition of the larynx indicated that there may have been œdema and spasm, but there was no history of it, and the case was under the observation, for the last three days of life, of Dr. Lynde, the house physician, and no whooping-cough nor spasm of the glottis was noted.

In this connection it was of interest, Dr. Northrup said, to refer to a similar case published in the *American Journal of the Medical Sciences*, July, 1883, entitled "Extensive Interlobular Emphysema and Abscess of the Lung, after Whooping-cough, in a Child of Two Months—Unique Case." The case was published by the speaker and was considered, at that time, "unique." He had since seen a specimen very like it in the Museum of the Royal College of Physicians, in London. These were the only cases of such extensive emphysema of which he was aware.

Dr. Northrup also presented a gross specimen, together with microscopic slides, demonstrating a case of

NECROSIS OF THE LUNG

(posterior marginal), in a case of pleuro-pneumonia and cerebro-spinal meningitis.

Roseman B——, aged two and a half months, was reported by the wet nurse to be "sick," but without any special symptoms. She nursed well, had no vomiting or diarrhœa, was somewhat restless, had slight cough and a temperature of 102° F. Two days later, temperature 104° F., respirations rapid, dulness over right chest posteriorly, abundant fine râles. Five days later, or seventh day of illness, the right side of chest was flat from apex to base over posterior half of lung, and bronchial breathing was present from root to base. Liver was depressed five centimetres below the free border of the ribs in the nipple line. Temperature 102° F. Respiration 60, painful, general pain on handling. Ninth day child refused to nurse, became fretful, with 103° F. temperature, pulse 160, and respirations 60. Anterior fontanelle prominent, pupils normal, no paralysis, no convulsions, head was drawn somewhat backward but not rigid. Failed rapidly and died on the tenth day. (Records of the case furnished by Dr. Geo. S. Lynde.)

Autopsy, fourteen hours after death.—Body poorly nourished; brain and cord covered with extensive pus and fibrin exudate, veins distended with blood and having upon their lateral margins borders of pus and fibrin. The exudate upon the cord was mostly upon the posterior surface. Ventricles were softened post mortem, velum interpositum covered with a distinct layer of pus and fibrin. Lungs: Right pleural cavity contained a jelly-like pad of pus and fibrin. This was an inch thick in the postero-lateral region, and wholly enveloped the lung except on its mediastinal aspect. The lung was compressed, and had in its lower and middle lobes a moderate amount of broncho pneumonia. Along the posterior margin was a mass of lung tissue of lighter color, firmer, more smooth upon its cut surface than the surrounding lung, four centimetres in length, two in width, and one centimetre in depth. It had the appearance of necrosis from infarction. Besides the marginal mass there were several scattered masses having much the same appearance. In and about

the necrotic areas were small abscesses or dilated bronchi, containing pus. These proved on microscopic examination to be collections of pus and fibrin in the interlobular connective tissue. Heart, endocardium, pericardium, peritoneum, liver, spleen, stomach, and intestines normal. Kidneys not congested, no areas of congestion or anæmia—appeared normal.

Microscopic examination.—The marginal area consisted of necrotic tissue. Skirting this on its pulmonary side was an irregular zone of tissue congested, having beside tortuous vessels, excessive exudation of fibrin and pus with abundance of blood-cells. The connective-tissue interlobular septa were densely packed with pus and fibrin, forming what appeared to be small abscesses or dilated bronchi referred to in the description of the gross appearance. No thrombosis was found. There was evidence of severe exudative inflammation in and about the necrotic area. At the posterior pleural margin there was found necrosis of the lung-tissue. The necrotic tissue, stained by Gram's method, showed micrococci distributed in the tissue and within the pus-cells.

DR. VAN SANTVOORD thought the case looked like one of pneumonia from inhalation of a foreign body (Schluckpneumonie).

DR. NORTHRUP said that he had found no such cause present in this case.

DR. H. M. BIGGS said that we do at times have such appearances as these in cases of foreign-body pneumonia. He had seen them occasionally at autopsies of idiots. He believed that, in these cases, micro-organisms were taken in with the foreign bodies, particles of food, or may be of fluid.

DR. NORTHRUP remarked that, in the case presented, one lung was normal, and would not this argue against the supposition of foreign-body pneumonia?

DR. BIGGS replied that it certainly must be very rare to have a foreign-body pneumonia confined to one lung. Referring to the specimen of interlobular emphysema, he said that he had never seen such a marked case in the human subject. He had recently, however, seen a very pronounced case of the kind in a cow.

The Society then went into executive session.

ANATOMICAL AND PHYSIOLOGICAL MEMORANDA FOR THE PRACTITIONER.—The average weight of the male adult is 65 kilos., or 130 pounds; of women, 53 kilos., or about 110 pounds. The average height of American recruits is 171.8 ctm., or about 5 feet 9 inches. The average height of well-built men is 172 ctm.; of women, 160 ctm., or 5 feet 9 inches and 5 feet 4 inches respectively. One inch of height should add two pounds to weight. The specific gravity of the body ranges from 0.9500 to 1.030. The heart weighs 260 grammes in women, and 330 (10½ ounces) in men, the average weight is 292 grammes. The period of its maximum weight is between the ages of fifty and eighty. The amount of blood in the body is one-thirteenth the weight of the body, or 5 to 6 quarts, or 11 to 12 pounds. A man dies when he has lost a fifth of his blood. The heart with each contraction ejects 180 grammes (6 ounces) of blood from each ventricle, at a pressure in the left ventricle of one-fourth of an atmosphere, equal to a column of mercury 200 mm. high. The heart sends all the blood round the body twice every minute, or in about thirty-five contractions. A deadly poison injected into a vein kills in fifteen seconds, on the average; injected under the skin, in four minutes. A cubic millimetre of blood contains 5,000,000 blood-cells in men, 4,500,000 in women. There are three hundred red cells to every one white blood-cell. The red cells have an average diameter of $\frac{1}{3200}$ inch, the white cells of $\frac{1}{2500}$ inch. The specific gravity of the blood is 1.055. The frequency of the pulse in the new-born is 150; in infants of one year, 110; at two years, 95; at seven to fourteen years, 85; in the adult man, 72; woman, 80. The respirations are one-fourth as rapid as the pulse.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

HYPNOTISM, ITS DANGERS AND USES—INFANT MORTALITY AND ITS RELATIONS TO PULMONARY TUBERCULOSIS.

PARIS, December 28, 1888.

AT the annual meeting of the Academy of Medicine, which was held last week, after the usual formalities of paying tribute to the memory of those members who died during the year, the report of the Annual Secretary was read and the names of those to whom prizes had been awarded were announced. Dr. Proust, in his capacity of the outgoing secretary, after having gone over the official matters of the Academy, referred to the subject of hypnotism, which has been occupying the attention of the lay as well as of the medical public. He began by citing some of the most curious phenomena of suggestion, the import of which he estimated in the following terms: "The facts of this order have given rise to apprehensions on the subject of the dangers of hypnotism. These apprehensions are exaggerated. It will suffice for me to add that, if one referred to the minute inquiries carried out on the question, the dangers which hypnotism would cause to society are more theoretical than true. Criminals have till now thought, and with some reason, that it was more prudent for them to operate directly and without any intermediate agent." He then recalled that the hypnotic state was not a necessary condition of suggestion, and that in certain neuropathic subjects it is not impossible to suggest, even when fully awake, hallucinations or orders, and added: "Moreover, suggestion in the state of wakefulness, does it not play a considerable rôle in all the acts of social life? Is it not the consequence of a mutual suggestion, a sort of infatuation which takes possession of assemblies or crowds at certain times, and gives rise to manifestations sometimes imposing, sometimes formidable, but always curious for the psychologist, of political or religious excitement? and in medicine, does not suggestion occupy a large place? I do not speak of the suggestion provoked during sleep, of which numerous works, particularly those of our confrères of Nancy, have demonstrated the indisputable efficacy. Do we do anything else than suggestion, when we try to raise the hopes of our patients? Every physician who has been taken up with the long and interminable maladies of the nervous system, where one exhausts, often without result, all the resources of the Pharmacopœia, knows the part which he can draw for the great benefit of the patient by an encouraging reflection or a good word. Thus Forbes has been able to say with reason that the imagination should be reckoned among the normal means essentially inherent to the practice of a new method of cure."

In connection with this subject, and by way of comparison, I may here refer to a discussion that lately took place at the Academy of Medicine of Brussels, on the propriety of employing hypnotism for the entertainment of the public, or even of the expediency of its use in medicine, as a therapeutic agent. The discussion was introduced by Dr. Gluye, who considered that the curative power of hypnotism is very limited. He recalled that, since 1843, Braid had not succeeded in diffusing his method, which he recommended even for the cure of tetanus and of rabies, notwithstanding the distinguished support of Professor Carpenter and others. On the other hand, alienists, who should be the first to employ hypnotism to produce sleep, calm the delirium, and transform the insane ideas into reasonable ones, do not appear to be in a hurry to use this means. In Germany, at least, the alienists are on the lookout for new narcotics. After morphine, chloral; they have now sulphonal, the effects of which are very much vaunted by them. Dr.

Gluye concludes his note with the statement that hypnotism is not without danger for the patients or persons in health to whom it may be applied; but the danger exists equally for the hypnotizer, whose imagination is easily excited, and whose judgment often becomes perverted, as pointed out by Braid himself. This results also from the curious fact that, in the country of Magendie, the creator of experimental physiology, some distinguished men discuss seriously the action at a distance of medicaments in hypnotized subjects. For me, adds Dr. Gluye, hypnosis is a state of artificial mental alienation, in the literal sense of the word. He is, therefore, of opinion that experiments in hypnotism in public should be interdicted just as much as the exhibition of lunatics.

Dr. Landouzy, in a memoir which he has just published, studies the Parisian mortality of infants aged from one day to two years, and its relation with tuberculosis. The author states that during the quinquennial period from 1881 to 1885, he ascertained the death of 67,330 children aged from one day to two years. As the general mortality amounted to 284.091, he makes the remark that the fourth of the Parisian mortality is furnished by infants from their birth to two years. Of these 67,330 infants who died in Paris in five years, 1,531 only were, according to the official reports, tuberculous. But this figure is much lower than the reality, according to Dr. Landouzy, who is engaged in researches on the other maladies which had determined the death of infants during this same period. He asks whether all the deaths caused according to the statistical report of the Prefecture of the Seine, by scrofula, meningitis, and the convulsions of infancy should not be included under the head of tuberculosis? In putting together all the cases, and by adding to them all the deaths from tuberculosis furnished by the report, Dr. Landouzy is of opinion that we are enormously below the true figure of the mortality by tuberculosis during the age of infancy. In fact, children who die of measles, whooping-cough, chronic bronchitis, pneumonia, gastro-enteritis, athrepsia, those which are affected with Pott's disease, diseases of the bones, white swellings, etc., are often nothing but tuberculous.

At the last meeting of the Council of Hygiene, a commission was appointed to inquire as to the expediency of replacing sulphur by antiseptic sprays for disinfecting localities contaminated by contagious diseases. It is known that the disinfecting properties of sulphur are at present much discussed. In Germany and in Russia they have given up the use of this product. They employ only the sprays of solutions of corrosive sublimate, which are followed by washings with carbolic acid, the furniture being previously removed and passed through a drying-stove.

WAS IT RHEUMATIC PERITONITIS?

To the Editor of The Medical Record.

Sir: Dr. Charles W. Packard's article, which appeared in The Medical Record of December 29, 1888, and entitled, "Was it Metastatic Rheumatic Peritonitis?" is a succinct statement of the course of a case of great interest to the general practitioner—the explanation of the symptoms is not necessarily dependent on the hypothesis of a rheumatic inflammation of the peritoneum having existed.

The doctor explains the absence of descriptions of the pathological appearances of rheumatic peritonitis by the statement "that there are no fatal cases." At the same time the case which he publishes presented symptoms of the greatest gravity, had the resistance of the patient been slightly less, the surrounding conditions not quite so favorable, or the physician less skilful, an autopsy would probably have thrown light on a case which "during part of its course seemed to fairly compel a diagnosis of peritonitis from some unexplained cause."

The facts stated by Dr. Packard, that the boy gave a history of previous chorea with subsequent articular pains, that on the occasion of his first visit he detected a slight systolic endocardial murmur, and also the age of the patient suggest embolism as the prime factor in the causation of the peritoneal symptoms, especially as we are assured by Dr. C. Hilton Fagge that an embolism in an artery may set up a peritonitis which may endanger life, and that in almost all cases the occurrence is complicated with a condition which Virchow has designated endocarditis maligna, on account of the severe and rapidly fatal course of some of the cases. These cases often have a rigor at the outset; there is a rise of two or three degrees, or more, in temperature, the pulse is quickened, the tongue dry, and vomiting or diarrhœa may be present. Articular pains are often complained of. Dr. Fagge ("Reynolds' System of Medicine," vol. ii., page 737) also states that examination of the heart at short intervals will detect variations in the physical signs, showing that acute changes in the valves are going on. In the case in point this seems to apply, as Dr. Packard remarks, that the slight heart-murmur heard on his first visit "had become much intensified by a fresh endocarditis."

An attack of acute rheumatic fever, of sufficient intensity to cause peritonitis of such violence would hardly be expected to disappear in a week, and with little or no anti-rheumatic treatment, the salicylate having been given after the peritoneal symptoms had almost completely subsided. Peritonitis, moreover, is a rare occurrence in acute rheumatism.

I think we can explain the symptoms best by assuming that a fragment became detached from the diseased valve and lodged in one of the arteries, in proximity to the peritoneum—the internal epigastric perhaps. This occurred two days before the doctor was called; irritation, congestion, and lastly inflammation, followed; the pain, at first most severe over the seat of the embolus, became general, and the symptoms of pronounced peritonitis followed. At a meeting of the New York Pathological Society, reported in The Medical Record, December 17, 1887, Dr. T. Mitchell Prudden remarks that in a very considerable number of cases of acute ulcerative endocarditis micro-organisms which readily produce phlebitis and peritonitis are present.

In writing this I do not desire to call in question the diagnosis, but the title of the paper appearing as an interrogation, prompted me to suggest what seems to me to be a satisfactory and rational explanation of the phenomena.

F. Percy Jenks, M.D.

409 Tenth Street, Brooklyn,
January 15, 1889.

CONCERNING RHEUMATIC PERITONITIS.

To the Editor of The Medical Record.

Sir: The interesting cases of so-called metastatic rheumatism recently reported recall a case with unusual features which fell under my observation in my student days. The case occurred in the practice of Dr. F. Findlay, of Franklinville, N. Y.

A young man was seized with typical symptoms of acute articular rheumatism. This was succeeded by the subsidence of the articular symptoms and acute pain referred to the region of the stomach, with repeated vomiting. It was especially noted that the invasion of the joints was followed by amelioration of the gastric symptoms, and *vice versa*. The persistence of the gastric phenomena finally necessitated the sole employment of the bowel for obtaining necessary nourishment, during which time his condition seemed past hope, and in the capacity of nurse I only left his bedside for food and sleep. The disappearance of articular and gastric symptoms was coincident, and apparently associated with the development of double parotitis which passed into the stage of suppuration. His illness was exhaustive in the extreme, his recovery tardy, if the expression be permissible, for he

has carried for over fifteen years an organic cardiac lesion which was a part of the early history, and which makes him almost an invalid to-day.

J. H. GREENE, M.D.

DUBUQUE, IA.

"THE POISON OF TYPHOID FEVER."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In support of Dr. Edson's paper in a recent issue of THE RECORD, I would offer a few observations of three epidemics I have had the good fortune to see:

No. 1. In the small village of Fulford, Lower Canada, a French workman from a neighboring town, after a few days' illness, died of typhoid fever. Situated near the house, and on the lower level was a spring from which the neighboring families obtained their water-supply. Three well-marked cases of typhoid took place in the family using the water, and five milder cases of fever, all no doubt due to the contamination of the spring with the excretions from the house above it. No other case occurred in the village, and the epidemic died out after the closure of the spring. The soil and also the water was found to be very rich in organic matter.

No. 2. In December, 1886, I had an opportunity, while visiting a colleague at St. John's, Lower Canada, of investigating an epidemic at that place. As in the previous one I was able to trace its source. A case of fever occurred in an old barracks a short distance above the town a month previous to the outbreak. The water-supply for the town was taken from the river just below the barracks. At the time of my visit my colleague had seen thirty well-marked cases, and he estimated that no less than one hundred others were suffering from fever of a continued type. The fever was most effectually stamped out by ordering families to boil both water and milk for drinking purposes. I may say that no cases occurred in the town of Iberville, which is situated on the opposite bank of the river, but enjoying a different water-supply. The country in this section is low, and the water dark from organic material. Malarial fevers are unknown in this locality.

No. 3. The third lot of cases I saw at Bath Beach. The disease was prevalent among the farmers of Long Island during last summer. I saw two characteristic cases here, and many guests in the same hotel were suffering from malaise, headache, and diarrhœa, with slight elevations of temperature. I was informed on good authority that there were twenty cases of typhoid at Bath during last summer. I was unable to trace the cause of this epidemic, though it would seem that one at least was due to bathing in the bay, where a large amount of sewage drifts in and may be seen at low tide. In fact, the disease was more prevalent among those who bathed a great deal. As in the previous epidemic, many of the milder cases improved as soon as they were put upon sterilized milk and water. I would summarize as follows:

First, I think the poison spreads with greater rapidity and becomes more virulent in proportion to the amount of organic matter in the water and soil.

Second, When the water-supply is infected with the poison, most of those drinking it suffer to a greater or lesser extent, though all may not develop the characteristic symptoms.

Third, It is of the greatest importance that the disease should be recognized at its earliest stage, the source of the poison located, and both milk and water sterilized before using.

New Instruments.

FORCEPS FOR REFRACTURE OF NASAL SEPTUM.

BY GEORGE B. HOPE, M.D.,

NEW YORK.

THE accompanying cut represents a forceps, to be used in connection with the Adams forceps, in the operation for refracture of the nasal septum. To those who have done the Adams operation at all frequently, a number of disadvantages have no doubt presented themselves; either an unnecessarily great violence in proportion to the seemingly slender obstacle to be overcome, must be employed; the feature of multiple fracture with a possible loss of a portion of the septum occurring in certain cases; but, beyond all, the difficulty of controlling, with any degree of certainty, a fracture which will obtain the most satisfactory results in the forced displacement.

In the action of one blade carrying a steel pin, which is received into a corresponding circular opening in the opposite blade, the septum is pierced by a line of punctures drawn at a sufficient inter-distance to map out a direction of fracture in exact conformity with the intention of the operator, and, in completing the separation of the bony continuity with the Adams forceps, any extreme force ordinarily necessary is obviated, to the advantage of the tissues concerned.

The forceps, made by W. F. Ford, of Hazard, Hazard & Co., are joined either by the sliding or fixed lock—the latter requiring less care in preserving the proper position of the pin to the opposing blade.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 13 to January 19, 1889.

BY direction of the President, and in accordance with section 1246 Revised Statutes, an Army Retiring Board was appointed to meet in this city, at 11 A.M., Thursday, January 17, 1889, for the examination of such officers as might be ordered before it. Detail for the board: Colonel JEDEDIAH H BAXTER, Chief Medical Purveyor, and Major CHARLES R. GREENLEAF, Surgeon. Par. 2, S. O. 12, A. G. O., Washington, January 15, 1889.

MUNDAY, BENJAMIN, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Sisseton, Dak., and to report in person to the commanding officer, Fort Sully, Dak., for duty at that post. Par. 2, S. O. No. 11, A. G. O., Washington, January 14, 1889.

ALDEN, CHARLES H., Lieutenant-Colonel, Surgeon, and Captain Edgar A. Mearns, Assistant Surgeon. Detailed for duty on Army Retiring Board to meet at St. Paul, Minn., at the call of the president thereof. Par. 7, S. O. No. 10, A. G. O., Washington, January 12, 1889.

HARRIS, HENRY S. T., First Lieutenant and Assistant Surgeon, will, upon the arrival of acting Assistant Surgeon Boyer, proceed from Camp Pena, Col., to the post of San Antonio, Tex., and report to the commanding officer, for temporary duty. Par. 4, S. O. 1, Headquarters Department of Tex., San Antonio, Tex., January 2, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 19, 1889.

DICKSON, A. H., Passed Assistant Surgeon. Detached from the Pensacola, and to the Atlanta.

OLCOTT, F. W., Assistant Surgeon. Detached from the Atlanta, and to the Vermont.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 19, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	4
Scarlet fever	277	58
Cerebro-spinal meningitis	2	2
Measles	377	30
Diphtheria	165	58
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

THE LATE DR. HOWARD PINKNEY OF THIS CITY.—The following tribute to the memory of Dr. Pinkney is offered by one of his many friends as supplementary to a notice of his death, which appeared some time since in THE RECORD: "Dr. Howard Pinkney left New York on May 5th, by the steamship Elbe, of the North German Lloyd line. He died in a railway carriage immediately after landing. He had just boarded the train for London from Southampton, and was found alone in a carriage, lying on his face. Dr. Ryerson, who happened to be a fellow-passenger, pronounced his death to have been from apoplexy. Dr. Pinkney had started upon his third visit to Europe. He was thoroughly exhausted by study and overwork, having all his life been closely wedded to his profession, and giving it more attention than was ever demanded by the most exacting sense of duty. He was the son of William Townsend Pinkney, and was born January 9, 1837, in this city, his father being at that time one of the ten Governors of Public Works. He was graduated from the Free Academy in 1856, receiving the degree of A.B. In 1860 he was graduated from the College of Physicians and Surgeons, with honors. He went from there immediately to Bellevue Hospital, where he served as House Surgeon until the breaking out of the Rebellion, when he volunteered as surgeon of the Ninth Regiment. He served at the battles of Ball's Bluff, Harper's Ferry, Antietam, South Mountain, and was several times assigned to special hospital duty, having at one time charge of the United States Army Hospital at Frederick City, Md. He there contracted typhoid fever, and was forced to resign. Having recovered, he again entered service as Assistant Surgeon, United States Army, and was located at Frederick City, Md. He also had charge of the Federal Hospital at Poolesville, Md., and the hospital at Keedysville, in December, 1862, when he resigned his commission. He was a member of the Order of the Army of the Potomac, and of the military Order of the Loyal Legion. He belonged to the New York County Medical Society, and represented it in London at the Medical Congress. He was a member of the Academy of Medicine, of the Physicians' Mutual Aid Society, and an honorary member of the Gynecological Society of Boston. He was for twelve years senior aufal surgeon at the New York Eye and Ear Infirmary, and established and carried on for seven years a non-sectarian free dispensary in connection with the Church of the Holy Trinity. He discovered the method of discolorizing iodine. In 1863 he married Miss Clara Schley, of Frederick City, Md., who died in 1877. He leaves one son, Dr. William H. Pinkney, who was his partner and associate in business."

SUDDEN DEATH IN CHRONIC DISEASES.—The *Revue Générale de Clinique et de Thérapeutique* contains some interesting cases of sudden death resulting from affections of the liver and pancreas, from tubercular peritonitis, and from operations in the hepatic region. Dr. Cénas met with a case of sudden death in a patient aged fifty-six, suffering from primary carcinoma of the bile-duct, which had existed for three years. It was only when the tumor invaded the pylorus that disturbance in the digestive organs appeared, and that the general condition became affected. M. Cénas considers that death was due to reflex action proceeding from the duct-wall, and reacting on a dilated heart. He bases this belief on the experiments made by MM. Brown-Séquard, Goll, and Tarchanoff (who arrested the action of the heart during diastole by irritating the semilunar ganglia), and on clinical observations which demonstrate the existence of syncope, diminished action of the pulse, and coldness in violent hepatic colic, and in different forms of irritation of the bile-duct. MM. Roussel and Jacquemard describe a case of cancer of the pancreas with dilatation of the stomach, followed by sudden death. The patient was a man aged forty-five, who had suffered from bronchial catarrh and pulmonary emphysema for ten years, and who died suddenly. The necropsy revealed cancer of the pancreas. The head of the organ was completely destroyed; the body contained carcinomatous nodules. The other organs were healthy. M. Roussel cites an almost analogous case, observed by M. Chavanis, and considers that all these observations indicate the existence of a special zone of sensibility, and that a traumatic or other lesion in this zone may cause death by depression. The following case of general tubercular peritonitis, resulting in sudden death, was reported by M. Alamartine. The patient was a man aged twenty-five. Three weeks after entering the hospital, on attempting to get up he fell suddenly to the ground, and died in a few minutes. At the necropsy seven or eight litres of fluid were found in the abdomen. The peritoneum, over which numerous granulations were scattered, was lined with false membranes, which covered and matted together all the viscera. The liver was inflamed, but contained no tubercles. The lungs contained a few tubercles, with some caseous nodules. The brain and meninges were healthy.—Paris Cor. *British Medical Journal.*

POISONOUS BLOOD.—M. Mosso, of Turin, having carried out a series of experiments with the blood of eels, finds that it possesses marked poisonous properties. Even to the tongue it has an insupportable acridity, and a very small quantity of the serum is sufficient to kill a dog. Half a cubic centimetre injected beneath the skin of a dog weighing thirty-five pounds, killed it in four minutes. At this rate, an eel weighing five pounds, would contain enough poison to despatch ten men. The blood of animals thus poisoned cannot be made to coagulate, just as after the bite of serpents. Fortunately the blood is inert when introduced *vid* the stomach, and it loses its toxic properties when heated.—*The Medical Press.*

THE INFLUENCE OF CARLSBAD WATER ON URIC ACID EXCRETION.*

BY SCHUMAN LECLERCQ, M.D.,

CARLSBAD, AUSTRIA.

MR. PRESIDENT AND GENTLEMEN OF THE NEW YORK ACADEMY OF MEDICINE: I am greatly pleased at the opportunity afforded me of addressing your honorable body this evening. As a member of one of the races which has contributed to the formation of that Anglo-Saxon people which has so distinguished itself in all quarters of the globe, and pre-eminently so in the United States of America, I feel that I am not among strangers, but among friends.

I am also conscious of the fact that I am standing before an august body, some of whose members have achieved a world-wide reputation and immortal fame in the domain of the healing art.

The subject which I take the liberty of bringing to your attention this evening is one which must, I think, possess interest to Americans, and especially to the medical men of this country, for Carlsbad is frequented more and more by your countrymen every year.

The beneficial effects of a "Carlsbad cure" in gout have been recognized by the profession for centuries past, but the theoretical grounds, upon which an indication for the "Carlsbad cure" might be based have been as vague as the theory of gout itself.

Professor Seegen was the first to establish a positive theory which might explain the efficacy of Carlsbad water in the treatment of gout. Seegen concluded from his investigations,[1, 2] that by the use of Carlsbad water there was a diminished nitrogenous metamorphosis and a diminution, amounting even to practical disappearance, of uric acid. It was generally believed that the effect of the Carlsbad water in gout depended upon the power to counteract the increased conversion of nitrogen, inherited or acquired by high living, this being the conception of the pathogenesis of gout which prevailed at that time. Coupled with the increased metamorphosis of albuminous compounds, the product of incomplete destruction of albuminous bodies, to wit, uric acid, was diminished possibly to subnormal, but at all events to normal proportions. Such was the theory in 1864. In the following year Professor Voit,[3] detecting the sources of error which led Seegen to his incorrect results, definitely refuted the theory of a lessened organic metamorphosis by the use of Carlsbad waters. With regard to this point, the extensive and lively discussion which then arose might be considered as having settled this question, and a recent attempt[4] to revive it must be deemed a mistake, all the more as the experiments yielded results which were contradictory in the different individuals experimented upon.

As for the second point, *i.e.*, the gradually diminished uric acid elimination, I have been unable to find any account of further investigation in this direction in the literature; at all events, Seegen's assertion, already referred to, continues to appear in the treatises on balneology and in those on gout which devote any considerable amount of space to the treatment of the disease with mineral waters.

* Read before the Section in Practice of Medicine of the New York Academy of Medicine, January 15, 1889.

At the suggestion of my friend, Dr. Herrmann, Director of the "Carlsbad Fremdenspital," I made a series of careful experiments with a view of ascertaining whether diminution of uric acid excretion under the influence of Carlsbad water, as accepted by Seegen, could be proven by our recent exact methods of quantitative analysis for uric acid. I made use of a method, recently advocated by Professor Haycraft[5] (of Aberdeen), slightly modified by Dr. Herrmann, and controlled by him with Ludwig's[6] method—the best we have—at Professor Huppert's laboratory of the University of Prag. Herrmann[7] ascertained that, although Haycraft's method gives comparatively too high results, owing to a simultaneous precipitation of some xanthine bodies (making a difference of 0.0029 per hundred urine), the loss of uric acid with either method does not exceed two per cent.; that it can, moreover, be thoroughly relied upon for clinical investigations and for the purpose of making comparative tests between a series of analyses. Nor is the accuracy of Haycraft's method invalidated either by the presence of albumen or of glucose.

Professor Haycraft's method consists principally in the following: By adding to the urine bicarbonate of soda and a solution of silver-nitrate of magnesia, previously rendered ammoniacal, a white gelatinous precipitate of urate of silver (and of phosphates) is obtained, which will not be reduced before it can be collected and washed on a felt-like filter properly made of asbestos and broken glass. The ready solubility in nitric acid of this urate-precipitate is used for estimating the silver by Volhard's method of titration. We then calculate the uric acid by its combination with silver. In order to avoid any negligence or mistake, I made the experiments on my own person. They were continued from September 19th to October 20th, and were arranged in this way. Having analyzed my daily amount of uric acid for five days, while placed upon a regulated diet and mode of life, I took Carlsbad water every day in gradually increasing quantities, and determined the amount of uric acid excreted during each twenty-four hours. The quantitative analyses were made every morning at the Carlsbad municipal laboratory, thanks to the kind permission of the mayor, Mr. Knoll, and the director of the salt-works, Dr. Szipöcs. The utmost care was taken in collecting the daily secretion from 6 A.M. to 6 A.M. of the following day. One hundred grammes of the well-mixed urine were used for two parallel tests. The quality and quantity of my food were absolutely the same during my experiments, admitting, however, such minute differences as might possibly arise from unimportant variations in weight of rolls, eggs, or in percentage of composition of my food. These factors could not by any possibility influence the excretion of uric acid to any considerable degree, for we have but to bear in mind that Lehmann,[8] in trials on his own person, ascertained that a strictly vegetable diet, when contrasted with a mixed diet, only revealed a difference of two grains uric acid per diem. For drinks I used wine taken from the same cask, besides water. With regard to the latter the quantity taken differed. I partook of it freely, first, because the important point to me was not to study the influence of common water on the excretion of uric acid; secondly, because the varying temperature of the atmosphere necessitated its free use; and, thirdly, because, even in taking an equal measure of water, I, like other observers, could not obtain a tolerable equal daily amount of urine. My *modus vivendi* and

diet were regulated so as to conform to that of Carlsbad patients, more especially of sufferers from gout. A short record will show this. I went to the spring at 6 A.M. and took the mineral water at intervals of fifteen minutes between each tumblerful (one tumblerful = 250 grammes), then followed an hour's quiet walking, after which I breakfasted off milk (300 grammes), a roll (average 81.5 grammes), and a soft-boiled egg. At noon I took a simple soup (puree of flour), beef (220 grammes), the same kind and quantity of vegetables (150 grammes), a roll, and 100 grammes of plain pudding. I took a long walk of several hours in the afternoon and supped at 7 P.M. off ham (70 grammes), one roll, a soft-boiled egg, and claret (100 grammes). I retired at ten.

The following table contains the result of my investigations (Table I.). It shows that the daily amount of uric acid excretion is upon the whole unaltered by the use of Carlsbad water and remains between 80 and 108 centigrammes a day, and that the total amount of uric acid excreted in a period of five consecutive days varies only between 4.023 and 4.890 grammes.

TABLE I.—*Daily Amount of Uric Acid Excretion.*

Date.	Twenty-four hours' urine in cubic centimetres.	Twenty-four hours' uric acid in grammes.		Carlsbad water.
Sept. 19....	1,345	1.046	Total amount of uric acid excreted in 5 days, 4.664.	None.
" 20....	1,350	0.878		"

" 19....	2,180	0.985		None.
" 20...	1,730	0.967		"

The few days (September 25th, 30th, October 1st and 6th) in which the daily excretion varied between 74 and 80 centigrammes, some smaller irregularities (such as a shorter walk) may satisfactorily explain the minimum diminution. I am also disposed to consider the slight increase, noticed when I took enormous quantities of the mineral water, as only apparently so, for with Haycraft's method some xanthine bodies are precipitated at the same time, and are estimated as uric acid. Owing to the ingestion of such considerable quantities of Carlsbad water as I took in the last days of the experiments, these xanthine bodies were liable to be washed out in a more marked degree and to appear more plentifully in the urine; the increase, at any rate, was so moderate that it hardly needs mention. I lost 2,950 grammes in weight, owing probably to the considerable exercise and the quality of my food, which was wanting in sufficient fat and carbohydrates, so as to imitate the usual diet of the gouty patient at Carlsbad, and owing perhaps also to the high temperature of the Sprudel water (165° F.), sipped as hot as possible—a concession to Cadet de Vaux's prescription. I should like to give you a short review of the results of the experimental researches of different authors with regard to the influence of various agents on the excretion of uric acid; for then it will be easier for me to illustrate my table. In the following list, made out so as not to encroach too much on your valuable time, I have ranged in a schedule as many investigators, according to their stand-point in this question, as I could find in the literature (Table II.). You will notice the great difference of opinion existing on every point, and readily agree that this question cannot be decided, at least not on the ground of the experimental material obtained hitherto, particularly as but a few of the results have a decisive value. Many of the analyses were made with inaccurate chemical methods, where errors varied, on account of the inconstant and uncontrollable loss of uric acid these methods involve, nor were all the tests made with the urine of twenty-four hours, or the series of experiments, with a few exceptions, was not long enough to yield results that could be compared. The diet, furthermore, was not regulated with the subjects experimented on by all authors. Finally, the increase or decrease of uric acid is not necessarily due to any extraneous factor as claimed, as similar fluctuations are also observed under normal conditions. This latter fact is illustrated in my Table. Although I was most careful in every point of the experiment, I could not, at times, avoid the considerable variations of uric acid excretion (which took place from one day to another) any more than other observers, though I admit that some of them were more fortunate than myself in this respect. This is all the more striking, as by my strict adherence to a uniform diet and mode of life, every possible source of variation, in so far as the excretion of uric acid is concerned, was thoroughly excluded, and certainly if any effects of the Carlsbad water were forthcoming, every opportunity was afforded for their exhibition in my economy. It should be remembered, however, that according to Neubauer,[10] the amount of uric acid, unlike urea, depends less on the food eaten than on special internal conditions of the organism, and that it changes greatly even in the normal state, and may vary from two decigrammes to one gramme within twenty-four hours, and also that Lehmann's [14] trials on his own person point to the fact that the nature of the food influences the secretion of uric acid much less than that of urea.* As, therefore, no external cause could influence the incontrollable daily variations in my uric acid excretion, I must ascribe them to internal causes, such as a regulating nervous influence. In fact, there are authors who ascribe the final regulation of uric acid production and excretion to the nervous system. According to Latham[9] gout is caused by a disturbance of the vasomotor centre, which influences the processes of organic metamorphosis, particularly in the nervous system. The atypical formation of uric acid in the muscles, as accepted by Ebstein[10] in gout, could be considered from the same stand-point.

While Garrod's thread experiment is in favor of an excess of uric acid in the blood of the sufferer from gout, and though Ebstein afforded the experimental proof that uric acid is the "materia peccans," Ebstein does not consider it necessary to accept a general accumulation of uric acid, at least not for the primary form of articular gout, because a *localised* retention of uric acid or a formation of uric acid in a wrong place—independent of increased production—could satisfactorily explain the development of gouty symptoms. Moreover, though everybody agrees that there is an increased excretion and formation[11] of uric acid in leucæmia, this disease is never combined with gout, which is a disease for which we must assume a disposition for a weaker resistance of certain organs against uric acid, either inherited or acquired.

All this fully proves that the indication afforded by the secretion of uric acid cannot always be taken as an index of the quantity formed in the system (Garrod), and the beneficial influence of a remedy in uric acid diathesis cannot possibly be proved by analysis of urine. Although

* Marés [13] concludes from his recent experiments that, while urea is derived direct from the decomposition of the albuminates of the food and circulating in the system, uric acid is a product of the active protoplasm, particularly of the glandular cells.

my experiments were made on a healthy person, the same conditions just referred to would prevail undoubtedly in gouty patients. If, however, experiments were made on these under the same conditions, the question would inevitably present yet greater difficulties, as the phase of the disease will lend still greater complications to the results. For these reasons I am inclined to believe that in future the influence of a drug on the increase or decrease of the uric acid excretion will not be conclusive with regard to its indication or contraindication in gout.

From a general review of the results obtained in my experiments I am compelled to say: A decrease of uric acid excretion under the influence of the Carlsbad mineral waters, as accepted by Seegen, is not shown, if controlled by the recent analytical methods, which secure a much more accurate test than the method of weighing uric acid after precipitation by hydrochloric acid, as used by Seegen. Thus the experimental investigations, on the base of which we were accustomed to explain the remarkable action of Carlsbad in the treatment of gout, have proved untenable on repetition of the experiments. This is perhaps of less importance now, as the ideas which formerly prevailed regarding the nature of gout are also undergoing a complete revolution, and one which will yet require much work before everything is made clear. At all events, the experiments which up to now so clearly and so convincingly proved the therapeutical action of the Carlsbad water must now be considered insufficient. Let me refer to those general physiological and pathological principles which might enable us to understand more readily the facts of practical experience.

Looked upon clinically, the well-known beneficial influence of a course with the Carlsbad waters on gouty patients points in two directions.

We notice first in these patients an amelioration in those symptoms which are explained as being occasioned by the presence of the "materia peccans," be it excessive or not, in the blood or organs; I do not mean to say that gouty "tophi" and deposits appear to become considerably smaller after a course with the waters; this can hardly be expected, since Ebstein[10] has proved that these deposits of urate are separated from the living tissue, which is yet capable of undergoing a metamorphosis, by dead tissue,—but we see for instance that albuminuria, inflammations of the renal pelvis, and nervous troubles, as hypochondria, melancholia, hysteria, which accompany gout, may be improved or disappear.

According to our view we explain these complications as being produced by excessive quantities of uric acid dissolved in the blood, hence we may justly say that by the imbibing of the warm alkaline water, which so rapidly becomes diffused in the blood, the conditions for a prompt discharge are more favorable. The diluted urine, which soon becomes alkaline, in a short time removes the surplus of uric acid circulating in the blood.

But we also see, secondly, that the gouty attacks, formerly frequent, are kept off for some time, or have become less intense, or are stopped entirely, after a course with the mineral water. With regard to this therapeutical effect we cannot get along with the former explanation of a washing out, but we must say the cause of the disease, the diathesis, seems mitigated.

Without attempting at present to explain this fact I shall content myself with saying: Since Minkowski's[18] thorough researches we know the liver to have a third function, besides the gall secretion and the glycogen formation, namely, the synthetic formation of uric acid. We know that sulphate of soda, so plentiful in our mineral water, considerably stimulates the gall secretion; it is likely that the influence of this salt on the liver is not only shown with regard to the gall secretion, but that in some way or another the salt affects also the uric acid formation. We cannot, however, as yet say in what way or how far it is the case, as no preparatory investigations exist in that line. But aside from the question of an excess of uric acid in gout, be it localized (Ebstein) or general (Garrod,[14] Ebstein[10]), we have in gout an anomaly in organic metamorphosis which is undoubtedly a complicated process, since modern investigation would tend to prove that uric acid is synthetically formed by xanthine bodies (Minkowski,[18] Mach[18]) and since this physiological formation of uric acid synthesis has been attributed to various organs. Charcot[16] already tried to connect gout with functional disturbances of the liver and Minkowski's

experiments tend to attribute the synthesis of uric acid to the same organ. The investigations of Kossel[17] make it appear that the xanthine bodies are products of splitting up of the nucleines, which derive from the substance of the nuclei of cells. In such animals (like birds and serpents), whose blood is rich in elements containing nuclei, and whose muscles are much richer in hypoxanthine than those of mammalia, we find a far greater production of uric acid. Chrzonszczewski[18] and Pawlinoff[19] noticed that the deposits of uric acid are found particularly in the neighborhood of the nuclei. The increased excretion of uric acid with the urine in leucæmia may be accounted for by the increase of white blood-corpusculi, which means an increase of the elements containing nuclei. Stadthagen,[11] however, showed that it is not the hypertrophy of the spleen in leucæmia which influences uric acid formation.

Such anomalies of metamorphosis have derived benefit from the Carlsbad cure, which I am inclined to ascribe to the great improvement which has taken place in the general bodily condition; and as the food is so important a pathogenetic factor in that group of diseases (diabetes, adiposity, gout, oxaluria, pyrocatechinuria, cystinuria), we might justly ask whether a faulty digestion of the stomach cannot promote the gouty process under certain conditions, of which we unfortunately know nothing, for intance, by the absorption of abnormous products of the food. Wine, for instance, has no influence on the increase or decrease of uric acid excretion; yet many close observers attributed a sudden attack of gout positively and with apparent right to a single imprudent use of wine in certain cases. How could we, then, explain this effect, if it were not for the well-established observation that alcohol has a direct protracting and thus pathological influence on the digestion of the stomach? From this stand-point also, *i.e.*, merely from the direct topical action of Carlsbad water on the stomach and the liver, which is the seat of the synthetical composition of uric acid, we could explain its recognized beneficial influence, at least in many phases and forms of gout.

Now, according to Garrod, the mineral waters are indicated in gout for the reason that the diathesis leading to its production is often closely connected with deranged hepatic function, and Ebstein recommends them particularly in those forms of gout complicated with plethora or gastric symptoms (see also Murray Forbes, Barlow, Parry and Sutton,[14] and Robson Roose[10]).

The compound action of Carlsbad water arises in the first place from the influence of the warm water itself, which, "when absorbed in large quantities, powerfully stimulates the process of the animal economy and increases the various secretions" (Garrod), secondly from the salts. With regard to these, the facts placed beyond doubt by experiments are the following: Sulphate of soda produces increased peristalsis and excretion of water, urine, and urea. The cathartic action cuts short, so to speak, complete digestion and absorption of the ingesta. Excretory matters, which would otherwise be retained (and possibly cause auto-infection?), are quicker eliminated than sub norma. Chloride of sodium greatly excites the stomach's functions and induces increase of urine and of the nitrogenous excretion; while carbonate of soda improves the digestive power of the stomach, increases peristalsis, and exalts the natural alkalinity of the blood. If now, by virtue of the properties of the constituents of Carlsbad water, there is an increase of peristalsis and diuresis, and an increased flow of liquids in the tissues, while plenty of out-door exercise and baths are taken, and less food—which is partly cut short, partly eagerly assimilated, owing to a hunger of the protoplasm—fewer products of the regressive metamorphosis will circulate in the blood and organs, while those that circulate are more easily eliminated on account of the diuretic effect and the increase of all secretory functions. Finally, the secretions are not only increased by the Carlsbad water, but also the pressure under which they are secreted is raised by sipping fluids. This is most likely due to nervous influence, for Kronecker[21] shows that a liquid taken in many small sips will for the time completely abolish the inhibitory action of the vagus of the heart. Brunton[22] calls attention to this fact "in consequence of which Carlsbad water, when taken in numerous sips for an hour or more, as at Carlsbad itself, is so exceedingly efficacious in hepatic diseases." This consideration will serve to assist us in explaining how certain predispositions of tissues, like the cartilage, to receive injuries in gout may be effectually combated with the Carlsbad mineral water. The increased pressure just referred to would be beneficial by increasing the "vis a tergo" in such organs as have a torpid tissue change, owing to the total absence of blood-vessels or their scant distribution at long intervals between the capillary vessels. The alimentary liquid being now easier renewed the conditions are not favorable for a deposit of urates. So much for the Carlsbad water.

The Carlsbad cure, which combines yet other factors, such as bathing, diet, and exercise, has been thoroughly studied in an excellent paper, read by your present chairman, Dr. Page,[23] before this distinguished society, some time ago, and I take the liberty of referring to it for further information. Hot baths in particular will be useful by increasing the activity of circulation and respiration. Increased consumption of oxygen and exhalation of carbonic acid will effectuate conversion of fat (adiposity being so often connected with gout) and decomposition of the constituents of the body containing nitrogen, with corresponding increase of urea in the urine. Even such a critical observer as Leichtenstern[24] acknowledges "the fact shown by multiplied experience that the products and residue of chronic inflammation and hyperplasia of tissue (hypertrophy of liver in gout) can be favorably influenced by warm baths, even of indifferent temperature, when supported by a corresponding change in diet, mode of life, bodily exercise, and the use of mineral waters." Then mud-baths will prove one of the most agreeable forms of local or general poultices to the gouty patient, and with regard to Russian baths it may be said that Tichborne[25] lately detected the presence of uric acid in the sweat secreted in Russian baths.

As a contraindication of the "Carlsbad cure" in gout I am inclined to determine those advanced stages of the disease with serious structural implication of the kidneys, or where cachexia has resulted, aside from such other general pathological cases where the cure is contraindicated anyhow (cardiac disease, considerable anæmia, carcinoma, pulmonary consumption, debility).

If, according to Garrod, the causes exciting a gouty fit are those which induce a less alkaline condition of the blood * or which temporarily check the eliminating power of the kidneys, the properties of the alkaline and diuretic Carlsbad water fully establishes its prophylactic value.

A good proof for the efficacy of alkalies is no doubt Cullen's[14] advocating them, and we can lay the more stress upon this statement, as, being a partisan of an entirely opposite idea on the nature of gout, he could not possibly be said to have been biased by theoretical reflections.

I am greatly indebted to you, Mr. President and gentlemen of the Academy, for the kindness with which you have listened to my paper.

MONUMENTS TO PHYSICIANS.—On October 28th two monuments were dedicated at Milan. One was dedicated to the memory of the late Dr. Gaetano Pini, the founder of the Milan Rachitic Institute, of the Italian Society of Hygiene, and of the Cremation Society. The other was dedicated to the late Dr. Agostino Bertani. He was a patriot, a follower of Garibaldi, and took part in all the principal battles for the independence of his country. He was the author of an important sanitary codex, which has been unanimously approved at the last session of the Italian Parliament.—*Ital. Cor. Chicago Medical Journal.*

PARISIAN VIEW OF AMERICAN MEDICAL COLLEGES.—While the organization of the American schools is imperfect and very rudimentary, nevertheless there are certain practices worthy of imitation; such as the methodical arrangement of the students' day, the weekly quizzes, directed by the professors' substitutes, and the six-weeks courses for physicians desirous of overhauling their scientific baggage.—*Progrès Médical—Philadelphia Medical Times.*

A CASE OF PERFORATION OF THE VERMIFORM APPENDIX, GENERAL PERITONITIS, LAPAROTOMY, ACCIDENT, AND RECOVERY; WITH REMARKS.[1]

BY ARTHUR M. JACOBUS, M.D.,
INSTRUCTOR IN GYNECOLOGY AT THE NEW YORK POLYCLINIC.

ROBERT W——, aged fifty, a boss painter, was first seen by me at 8 A.M., Tuesday, October 23, 1888.

The patient gave the following history of his present trouble. For several months past he had had, as a rule, distress in the right iliac region after drinking coffee; he had never had any real painter's colic, but suffered from constipation; on the evening previous to the attack, while descending the Metropolitan Opera House stairway, he was seized with distress in the lower part of his stomach; on Monday, October 22d, he was busy all day fresco-painting, though the uncomfortable feeling in his bowels continued; about nine o'clock that evening he was suddenly taken with violent intestinal cramps, the pains being principally on the right side, and accompanied with nausea; he supposed it was an attack of acute indigestion, and at once drank some Jamaica ginger, lay down upon a lounge, and had a mustard-plaster applied to the abdomen. This gave him some temporary relief. His wife, not feeling well, then went to bed, but on awakening at about 11 P.M. she heard her husband groaning in the dining-room, and going there found him still on the lounge, lying on his back, with the knees drawn up, and suffering intensely with severe colicky pains and chilly sensations; he was unable to walk, but his wife, with assistance, succeeded in getting him into bed. She continued the mustard-plasters, applied hot bottles to his extremities, and used various household remedies, so that by 2 A.M. he was fairly comfortable.

At 8 A.M. Tuesday, when I saw him, he was in bed, lying on his left side, with the knees drawn up; had an anxious countenance, a suppressed cough, gave forth frequent groans, and complained of increasing pains throughout the abdomen, but more severe on the right side. His temperature in the mouth was 100⅕° F., and the pulse 98. His appetite was poor and the bowels had not operated for several days. There was slight general tympanites, with scarcely perceptible dulness below the cæcum. Slight pressure, or percussion of the abdomen, caused outcries from the patient and gave him great pain.

Notwithstanding the fact of the low temperature and pulse, the diagnosis of appendicitis with peritonitis, from probable perforation, was unhesitatingly made. As the condition of the patient was not grave enough to warrant an immediate operation, a palliative plan of treatment was adopted. Absolute rest in bed, in a recumbent position, with hot applications constantly applied to the abdomen, was directed. These were made by saturating flannels in a pint of hot water containing one teaspoonful of turpentine, then wrung out, placed on the abdomen, and covered by a hot-water bag. Great relief was experienced by the use of these applications, while cold could not be tolerated.

A seidlitz-powder was ordered, to be repeated, if not effective, in three hours, and followed in the morning by a glass of Victoria Hunyadi water.

For the pain and fever, morphine, gr. ⅛, and antipyrine, gr. viij., were directed to be given every three hours, as necessary. Wednesday morning the patient reported that he had passed a comfortable night, and had had two soft copious stools. His temperature was 99⅜° F., and pulse 85. There was still slight tympanites, with tenderness of the abdomen and dulness on the right side, but apparently a generally improved condition of the patient. He was not seen again until early Thursday afternoon, when, at a glance, it was evident that he was worse. He had but little pain, but his countenance was pale and pinched, the

[1] Paper read and patient exhibited at a meeting of the Northwestern Medical and Surgical Society, New York, December 19, 1888.

suppressed cough more prominent, the temperature 100½° F., and the pulse 76. His wife stated that on the afternoon previous, being nearly free from pain and making light of his trouble, he had stopped the medicine and applications, and had sat up, out of bed, for some time, until a recurrence of the colicky pains compelled him to return to his bed. The abdomen was now found to be unusually sensitive, with increased tympanites and a fulness above the crest of the right ilium. Deep-seated dulness was detected at this point, on careful percussion, and appeared to cover a spot about the size of a hen's egg. There was now no doubt that an operation was necessary, but as it was getting late in the day, the area of dulness small, and the condition of the patient fair, I decided to wait until morning before submitting him to an operation.

The delay proved dangerous, for about 6.30 the next morning, Friday, the patient was awakened by a terrible burning pain in the right inguinal region, which radiated over the whole abdominal cavity and rapidly grew worse. The family hastily sent for me, and the summons too well told me what had happened. It was evident that a perforation had probably taken place, Monday evening, that a protective sac had formed, that though the patient was quite well Wednesday, a sneaking peritonitis had been developing, and that this new attack was the result of the bursting of the sac and a full-blown general peritonitis. At 7.30 A.M. the patient had a temperature of 99⅘° F., pulse 85, and was given an opiate to relieve the intense suffering. The fulness which was noticed in the inguinal region the day before had disappeared.

Having the sole interest of the patient at heart, I sent for our fellow-member, Dr. W. Gill Wylie, an expert laparotomist, to perform the operation, rather than do it myself. The choice was well made, as the result shows. At 9 A.M. the patient had a chill, and a temperature of 101¼° F., with increasing tympanites, pain, and nausea. At 11 A.M. he was sweating profusely, had a temperature of 102° F., pulse 110, and was in partial collapse. Owing to other engagements Dr. Wylie was not able to commence the operation until 11.30 A.M., when it was performed, under ether, with the assistance of his brother, Dr. R. H. Wylie, and myself; the patient's abdomen, and the hands of the operator and assistants, having been previously washed in a solution of bichloride (1–2,000). It consisted in cutting an oblique opening down to the peritoneum just above the crest of the right ilium and, later, another opening, in the median line, just below the umbilicus. The peritoneum, deeply congested, presented in the lateral opening and was bulged out by an indistinct mass of intestines. A hypodermic syringe withdrew some serum, but no pus. For fear of injuring the intestines, which appeared to be matted together, and in order to do a thorough operation, Dr. Wylie then made an incision in the linea alba, below the umbilicus, when again the peritoneum, greatly congested, protruded from the opening. Upon incising it, a little gas and a pint or more of purulent serum, with large flakes of lymph, escaped. There was a fetid odor, but no discoverable fæces. The peritoneum was inflamed and granular, and the intestines, excepting those in the pelvis, were entirely matted together by quite firm adhesions.

The wisdom of the median incision was now apparent, for in no other way could the adhesions have been safely broken up, or the whole abdominal cavity thoroughly cleared of the septic material which had escaped, or been developed, in it. Dr. Wylie introduced his hand in the median opening, and very carefully broke up the adhesions and pockets of purulent collections between the intestines. The appendix was found pointing upward (on the cæcum), and firmly fixed in a (ruptured peritoneal) sac, which latter readily admitted the finger. A hard body, one-fourth by one-half inch in size, apparently a bean, was discovered lying beside the appendix, in the sac, having evidently recently escaped from it.

The lateral opening in the abdomen was then made complete, and the whole cavity thoroughly washed out with plain boiled water at a temperature of 110° F. About five gallons were run through with a fountain-syringe, having a glass nozzle one foot in length, and as thick as your finger. The doctor during the douching separated the intestines, in every part of the abdomen, with his hand. When the water ran clear the douching was stopped, enough water left in the abdomen to float the intestines, and the wounds sutured in the usual manner with interrupted deep and superficial silk sutures. A glass drainage-tube was of course inserted in each wound; that in the lateral being placed in the sac containing the appendix. *The appendix* being fixed, the bowel empty, and no fæces escaping, it *was not disturbed or sutured.* Iodoform and absorbent dressing, with adhesive plaster and bandages, were applied as usual, and the patient left in charge of a trained nurse.

The operation lasted less than one hour and the patient rallied nicely from it. Less than two hours later the patient's temperature and pulse had fallen from 102° F. and 110, respectively, to a temperature of 98⅘° F. and a pulse of 90. For the next twenty-four hours the temperature averaged 99° F., the pulse 85; the patient was comfortable without opiates; there was a profuse continuous serous flow from both tubes, and from the lateral tube a fecal odor escaped. The kidneys acted regularly from eight hours after the operation.

To counteract the great irritation and discharge from the peritoneum, and to prevent vomiting, nothing was given in the way of drink or food for the first twenty-four hours.

During this period there were attempts at retching, but the patient controlled them by his will. From this on the patient was gradually able to take, every three hours, a teaspoonful or more of cold water, previously sterilized, or Brush's kumyss. The latter was a great success, for he was not able to take anything else for the next four days, without attempts to vomit. Later on the diet-list was increased by boiled milk (sterilized), milk-punch, peptonized milk, and black, or beef, tea.

The second twenty-four hours the patient was quite comfortable, slept well at intervals, had an average temperature of 100½° F., a pulse of 90, and the wounds looked well; the lateral one discharging freely a chocolate fluid, slightly feculent. In the first half of the third twenty-four hours the patient became uneasy, had an anxious, pinched look, much abdominal pain, and tympanites, which was increasing; and the temperature ran up to 101⅘° F. and the pulse to 102. The central drainage-tube, having ceased to discharge, was removed, and a seidlitz-powder administered, to which was added, at Dr. Wylie's suggestion, a teaspoonful of Epsom salts. This was followed in three hours by an enema and a hard stool, and in the next few hours by two large diarrhœal movements, which had a most excellent effect upon the patient. He became more comfortable, there was less tympanites, the temperature fell half a degree, and the pulse from 102 to 88. In the fourth twenty-four hours the lateral wound was irritable and painful, and the temperature, which had risen, fell to 100½° F., after the integument was separated and a little pus had escaped.

In the fifth twenty four hours the patient had apparently passed all danger, his appetite was improving, the quantity of food was increased, there was but little tympanites or tenderness, he had a natural movement, after an injection, and the temperature fell to 99° F. and the pulse to 78.

In the sixth twenty-four hours the patient was still better, and the family were told that he was now entirely out of danger, and, barring accidents, which could not occur without gross carelessness, he would certainly get well.

As the central wound looked firm and dry, the silk sutures were carefully removed, extra-long adhesive straps applied, and a firm pad of cotton with a bandage added. The patient was also cautioned against any attempt to

strain, or sit up in bed for any purpose whatever. In the afternoon of this day, while rejoicing over the blessings of successful surgery, my feelings were rudely upset by a hasty summons to see the patient, who, it was said, was dying.

On entering the house everybody was found in a panic, and nothing could be learned until the nurse recovered sufficiently to tell me that the abdomen had burst open and that the bowels were all out. I was as nearly upset as the nurse at this state of affairs, and the shock received was beyond description. However, learning that Dr. Wylie had been sent for, and would share my responsibilities in the matter, I felt easier. The patient looked badly, moaned constantly, and thought his end had come, but acted quietly withal. I learned the next day from the patient, after the nurse had left, that the accident happened after a dispute between himself and the nurse as to the propriety of his taking food more freely. She reluctantly yielded, gave him a glass of milk, but would not assist him to drink, so he, with much difficulty, raised up on his elbow, in a strained position, and the central wound burst open. He at once told the nurse that something had given way, but she said it was nonsense, paid no attention to his alarms, until she saw by his countenance and groans that something really was wrong; and then, on removing the bed-clothing, was greatly astonished at seeing his bowels protruding from under the bandages. When I arrived, about twenty minutes later, about half a peck of intestines, slightly warm, were found lying upon his abdomen. The bandages and plasters were quickly removed and the bowels wrapped in hot wet towels, preparatory to washing them in plain boiled water. It was then easy to see the numerous patches of adhesions which Dr. Wylie had broken up at the operation. The intestines in the bite of the wound looked dark and as though they had been pinched in a door. The rest were covered with iodoform, cotton, plaster, and pus. I then discovered that the pus came from several small mural abscesses in the superficial fascia.

The infection of the parts by the septic fluid, at the time of the operation, undoubtedly caused these abscesses, and, secondarily, the bursting of the wound.

In several places it was very difficult to remove the cotton from the intestines, even after prolonged soaking, and, as it seemed to be embedded in granulations, what could not be pulled away or cut off was returned with the bowels. Owing to the rigidity of the abdomen, as it was thought best not to etherize, it required considerable pressure and manipulations, on the part of myself and the nurse, to replace the bowels, particularly the last loop, which was distended with gas. Shortly after replacing the intestines, Dr. Wylie arrived, and then quickly sutured the wound with silver wire, and all was well again. The patient had had a free watery passage in the morning, from the seidlitz and Epsom mixture, and a few hours after the accident another stool. In the evening he had a temperature of 99° F., pulse 108, and was suffering from constant griping pains in the bowels. Morphine, gr. $\frac{1}{4}$, was then given hypodermatically. This was the only time he had an opiate after the original operation.

In the first half of the next day, or seventh twenty-four hours, the temperature had gone up to 100$\frac{1}{5}$ F., pulse to 100, and there was much pain and tympanites, with symptoms of fresh peritonitis. The seidlitz-mixture was again given, and in the next few hours much flatus escaped from the rectum, and he also had two watery stools. The temperature and pulse then fell to nearly normal, and the patient became very comfortable.

The next day, the eighth after the operation, the temperature and pulse became normal and remained so. The glass tube in the lateral wound, and which had gradually been forced out, was then removed. Both wounds, superficially, were slow in healing up, owing to slight sloughs in the subintegumentary fascia, but in the end the union was firm, and there was no tendency to hernia.

During the next week the patient was frequently distressed with tympanites, but a dose of the seidlitz-mixture quickly gave him relief. There was the usual costive and paretic condition of the bowel after peritonitis. For this strychnia (gr. $\frac{1}{60}$) was given, in Keyes' tonic (hydrarg. bichlorid., gr. $\frac{1}{64}$, and tr. cinch. co., 3 j.), after each meal, with excellent effect. Within three weeks after the primary operation the patient was able to walk about the house, and about a week later, out-doors. As a support an elastic abdominal bandage, having a covered sole-leather pad in front, was applied, and directed to be worn when walking.

The history of this case has been given rather fully, because it is believed that it will therefore be more instructive to the beginner, and possibly to the experienced surgeon also, as detailed histories are to the former what experience is to the latter.

In reviewing this case, it must be evident to all that the man would have died without an operation; and further, that the ordinary lateral opening, and failure to enter the abdomen, break up the adhesions, and wash out the cavity, would have ended likewise. Even as it was, the operation should have been performed at least one day earlier, and would have been, had I not been misled by the apparently favorable condition of the patient on the second day, and also by the perusal of an article (recently published) advocating delay, on the ground that typhlitic diseases are extra-peritoneal, and not likely to set up peritonitis or rupture into the peritoneal cavity. It then looked like a mistake in diagnosis, and as though it was a simple perityphlitic inflammation undergoing resolution.

If one studies the cases of inflammation of the appendix, and of perityphlitic abscesses, reported by Bull in *New York Medical Journal*, vol. xviii., 1873, and New York MEDICAL RECORD, vol. xxix., March 6, 1886, Burchard in *New York Medical Journal*, vol. xxxiii., 1881, Weir in New York MEDICAL RECORD, vol. xxxi., 1887, Sands in "Annals of the Anatomical and Surgical Society," Brooklyn, vol. ii., 1880, and *New York Medical Journal*, February 25, 1888, and also the cases reported by others, he cannot help believing that the question of location of these diseases, *i.e.*, whether intra- or extra-peritoneal, is given more prominence and enters more largely into the method of treatment than is judicious. As a result of this, many physicians and surgeons temporize and wait for a supposed extra-peritoneal abscess to kindly come to the surface and be opened; meanwhile, many a valuable life (even in our own profession) has been lost by an insidious general peritonitis or pyæmia, or the bursting of the abscess internally, with the same result. It is gratifying to reflect that nearly all the writers above referred to, and many other prominent surgeons in America and Europe, are not advocates of this policy of waiting for something to turn up, but, recognizing the fact that, though nature often does her best to wall up the poisonous material resulting from inflammation or perforation of the appendix or cæcum, she is, without prompt surgical relief, almost always an entirely incompetent and fata operator. The late Dr. Sands and others have admitted, and the operations and post-mortems in such cases confirm their statements, that in the larger proportion of perityphlitic abscesses, seeds, fæcal concretions, etc., are found within them, thus proving that the disease originated in either perforation of the adjoining and adherent appendix or cæcum.[1] Further, many of these cases give histories of long-continued distress in the region of the cæcum previous to the final abscess, or general peritonitis. These are the cases of circumscribed typhlitis which often resolve, only to return again, and eventually end fatally. The clinical evidence given by Dr. Weir, founded on a large collection of cases, is indisputably in favor of

[1] After reading this paper, the writer's attention was called by Dr. W. T. Bull to a paper recently read by him before the Medical Society of London, on the Surgical Management of Typhlitis and Perityphlitis. See The Lancet (London), November 10, 1888. This paper, which was discussed by Drs. Weir, Treves, and others, gives positive evidence on the disease starting in the appendix and being intra-peritoneal, and is also a strong plea for early operation.

perityphlitic diseases originating and being in the peritoneal cavity.

Having attempted to prove that the so-called extra-peritoneal abscesses are admitted to have originated from perforation of the appendix or cæcum, the writer will now quote from an original worker in this field of anatomy to show that these organs are completely surrounded by the peritoneum and in its cavity. Frederick Treves, Hunterian Professor at the Royal College of Surgeons and Surgeon and Lecturer at the London Hospital,[1] states "that in one hundred specimens examined, I have never found the posterior surface of the cæcum uncovered by peritoneum; I have never found it attached by areolar tissue to the iliac fascia; and I have not met with one single example of a *meso-cæcum*. I am very much disposed to doubt the existence of such a fold as the last named. Now in every instance that I have as yet seen the cæcum has been entirely enveloped on all sides by peritoneum, and has been free in the abdominal cavity." He also says that the cæcum may be above or below the pelvic brim and that it and the appendix have been found free in the left and other portions of the abdominal cavity. Finally, Treves says: "The relations of the cæcum to the peritoneum are of great interest in surgery and medicine, the part being so frequently the seat of trouble. It has, I notice, been recently proposed that, in certain inflammatory conditions of the cæcum, the gut be reached by an incision from the loin, the incision not to include the peritoneum, but the gut to be exposed at its hinder part, just as the external iliac artery is exposed in the extra-peritoneal operation for ligature. I would take the liberty of stating that such a procedure is anatomically imposible." Such strong statements, from such a source, founded on original work, and not handed down from one text-book to another, disprove thoroughly all theories or statements founded on a few post-mortems of the pathological, or diseased, condition of the parts. The writer does not wish to be understood as saying that abscesses may and do not form, as the result of exposure, injuries, etc., in the iliac fascia, outside of the peritoneum, or within the peritoneal cavity, behind the cæcum and elsewhere, and, by protective adhesions, practically become extra-peritoneal, and so reach the surface. We have similar examples of pus-sacs, formed by limiting adhesions, in the pelvic or pleural and other cavities, yet they are still intra-peritoneal, or intra-pleural, etc., as the case may be, and should be opened, if possible, by direct means, without reopening the cavity from which they originally sprang. Given a case of perityphlitic abscess which can be opened direct, through the loin, and in which we know positively that there is no associated peritonitis, the surgeon would be foolish indeed who would think of giving exit to the pus via the open peritoneal cavity. But how can we feel assured, in the majority of instances, that such is the case?

The danger is, that those who are prejudiced, or unfamiliar with the subject, are inclined to consider these abscesses as almost harmless, in respect to their liability of causing septic peritonitis by contiguity, or rupture into the open peritoneal cavity, and thereby fail to diagnose the peritonitis, which is frequently masked, or realize the true condition, until too late. Even the late Dr. Sands, in his paper first referred to, reports several deaths (from the abscess rupturing in the peritoneal cavity), and yet, in his last paper, referring to the burrowing of these, so-called, extra-peritoneal abscesses, says, "But in no one of these cases does the peritoneum give way;" and, still more strangely, immediately states, in the next sentence, that "when it does, and the contents of the abscess enter the serous cavity, death from acute septic peritonitis is almost inevitable."

In examining the histories of the cases of extra-peritoneal abscesses reported in the various journals it will be seen that among those who survived the delay in operation, and were finally operated upon in from one to two weeks after the commencement of the last acute attack, many did not survive the mere opening of the abscess in the loin. How do the advocates of the late operation account for deaths after the opening and draining of an abscess, not connected with a vital cavity? I think the answer is, that some are nearly dead from shock, septicæmia, or pyæmia at the time of the operation, and the rest die from an infiltrating septic peritonitis, resulting from failure to recognize the true pathological condition and, necessarily, failure to enter the abdominal cavity, break up the adhesions, and wash out the cavity, as Dr. Wylie did so successfully in the case here reported.

In view of the foregoing, it appears to the writer that, as the affections of this region are almost always due to inflammation or perforation of the appendix or cæcum, either recent or remote, and accompanied, with scarcely an exception, by septic peritonitis, there is but one proper method of procedure in all cases not promptly yielding to rest, laxatives, etc., and which are progressive, and that is, to perform laparotomy promptly—not later than the second or third day, if possible—open the abscess, give exit to the offending discharge of foreign bodies, break up all adhesions, and then thoroughly wash out the abdominal cavity, and drain.

The chief reason why this is not the practice of the general surgeons is their fear of opening the peritoneal cavity. In the hands of the gynecological surgeons of to-day this has become an almost daily task, and one in itself practically devoid of danger. The danger, when it occurs, lies not in the laparotomy, but in gross carelessness in performing it, or in the gravity of the disease for which it is performed. Laparotomy for peritonitis from typhlitic diseases is certainly much simpler than when it is performed for the removal of tumors, pyo-salpinx, extra-uterine fœtation, etc., and yet there are gynecological surgeons who have performed some of the latter operations hundreds and hundreds of times without a death, and frequently, too, in cases with associated septic peritonitis. Is it not then fair to suppose that an operation for perforated peritonitis, performed within the first three days of the attack, ought, in at least seventy-five per cent. of the cases, to terminate successfully. Tait[1] reports twenty-six cases of suppurative peritonitis treated by abdominal section, washing out, and draining, and with most excellent results, as he saved eighty-five per cent. of the patients, the most of the deaths occurring in the first few operations. This is a result to be proud of, and I doubt not that, with early operations, whether for abscess or peritonitis, he will improve his record and others approach it.

Excepting for abscesses which approach the loin and in which there are absolutely no symptoms of peritonitis, there can be no question that the incision in the abdominal cavity should either be over the caput coli, as recommended by the late Dr. Sands, or in the median line below the umbilicus, as performed by many others, and not by the usual oblique operation. It is true that "the vertical incision over the cæcum affords the easiest access to the parts presumed to be diseased," but it has several disadvantages over the median operation; first, such an incision, "four inches long, beginning at a point half an inch above and to the outer side of the middle of Poupart's ligament," necessarily involves the cutting of important blood-vessels, etc.; second, it is more likely to result in a hernia; third, if there be extensive adhesions about the cæcum, like in the case reported, there is more danger in wounding the intestines. The median operation enables one to attack and separate the adhesions from their border; it is simpler; there is less hemorrhage; and, finally, it offers better facilities for washing and draining the peritoneal cavity. If necessary, the ab-

[1] See New York MEDICAL RECORD, vol. xxxiv., November 10, 1888.

dominal wall may still be punctured over the cæcum and a drainage-tube inserted in the sac by the appendix. As Sands, Weir, and others do not deem it so important, in ordinary cases of perforation, at least, to suture or excise the appendix, the question of seeing instead of feeling the latter is not vital. In the case referred to in this paper it will be seen that the appendix was not disturbed, or sutured, and I doubt not that if it had been torn loose, or meddled with, the result would not have been so good; for though there was a fæcal odor escaping for several days, the fistulous opening closed up promptly. Perhaps this has been a factor in some of the fatal operations. With large openings, or gangrene of the bowel, suturing, or resection, would, as a matter of course, have to be done. The question of suturing the abdominal wound, and draining by tube or leaving it open, is also a mooted point.

The process of draining and healing by open wound is certainly more likely to prove dangerous to the peritoneum, and result in a hernia, than the immediate closing of the wound and drainage by glass tubes; and as the latter is the method (when necessary to drain) that is pursued so successfully by gynecological surgeons, it would seem that it was the better plan. It would appear that all surgeons would agree that the abdominal cavity should be washed out whenever it has been penetrated by septic material; but yet such is not the fact, for Dr. Weir (who was one of the first surgeons in this country to adopt Listerism), in his most valuable article previously referred to, is inclined to think douches dangerous, and when summing up, after referring to the time of the operation and progressing general peritonitis, says "that if pus is thus recognized it should be evacuated, and a drainage-tube inserted without toilet of the peritoneum." Dr. Weir was inclined to attribute an unfavorable effect to the douching, particularly after using the hot water, as recommended by Wylie. He admits, though, that the use of the tube only in the pus-cavity is a less surgically correct procedure. Dr. Weir used the hot abdominal douches, for their stimulating as well as cleansing action, in a case resulting fatally, and noticed a deterioration of the patient's pulse, but adds, "it may have been that the heat was too great, as at first it was sufficient to be decidedly uncomfortable to my hands and those of my assistant colleague, Dr. Bull." He further says that "the patient was much shocked by the operation and died four hours thereafter, with a temperature running up to 105° F. before death," and that "the autopsy revealed nothing of additional moment."

How the death of this patient can be, even indirectly, attributed to hot douching, even with such hot water, I cannot understand, for it was a case of recurring appendicitis, with several perforations, general peritonitis, and partial collapse, operated upon on the fifth day, after having been treated by other physicians, then removed to a hospital and examined under ether, the day previous to the operation. Having seen such excellent effects in a number of instances after hot abdominal douchings of sterilized plain water, I should be very sorry to hear of their rejection as being injurious. Douchings are absolutely necessary, and plain sterilized hot water, while efficient, is safer than solutions of bichloride, etc., in the peritoneal cavity. A valuable point made by Dr. Wylie, and adopted in the case reported, is the filling of the abdominal cavity with hot water, previously to closing the wound, for the purpose of floating the intestines and preventing new adhesions. In using the douche one should use a thermometer, and the temperature of the water be not judged by the hand. For safety, it would appear that a temperature of 105° F. is high enough. In purchasing a thermometer it would be well to test it, for in looking over a choice stock in a prominent drug-store recently, I noticed that there was a difference of 12° F. among several lying in the same atmosphere.

The writer had intended to refer to the needless danger in using an aspirator to make a diagnosis and determine the question and place of operation, but time will permit of merely a brief reference to the fact that Tait and many others condemn it, and state that all laparotomies are more dangerous in proportion to its frequent use. I think the records of the cases of typhlitis, etc., wherein it has been used, will confirm the statement that it was often inefficient, as well as dangerous, and that *the operation was necessary, pus or no pus.* Before closing this paper, the writer desires to refer briefly to the modern method of treating peritonitis, by laxatives and but little or no opium, instead of by the old method of extreme narcosis. Peritonitis, even the so-called idiopathic form, if there be such a thing, is necessarily a serious disease, but when the patient has not only to fight it, but the non-operating opium-poisoner, it means certain death in a large percentage of cases.

Many of us have certainly seen such cases, in hospital and private practice, and which might have been cured by the laxative treatment recently originated, I believe, by the gynecologists. I have seen several instances of general and pelvic peritonitis where it appeared certain that without free catharsis the patient would have died from cardiac or respiratory paralysis, from excessive tympanites, or from septicæmia, in purulent cases.

In the case reported, laxatives had a most salutary effect, not only before the operation, but after it and the accident. It will be seen by the history that there was extensive purulent peritonitis, and yet the tympanites, pain, temperature, and pulse were kept down by frequent doses of salines.

Opium has had its day, as a cure-all, and it seems now only a question of what kind of laxatives shall we use. I have found, with others, that a seidlitz-powder, in divided doses, is useful to allay the vomiting in these cases; but to effect catharsis, one must often give one and a half powder at a dose, or else repeat them in two hours. In either case they are bulky, sometimes rejected, and, unless quick action takes place, they are apt to increase the distress and tympanites. Dr. Wylie adds a heaping teaspoonful of Epsom salts to each powder, as was adopted in this case, while others give larger doses of Epsom salts singly. In several instances of obstructive peritonitis, when seidlitz-powders failed, and there was extreme tympanites, an ounce of castor-oil, given in hot milk, saved the patient, as I think, from certain death. If the salines have no specific action, and the object is merely to drain the peritoneal cavity, or congested blood-vessels, of their septic contents, it would seem as though some of the vegetable cathartics would at times answer better. Aloes and croton-oil have been used by some physicians, but I would suggest Clutterbuck's elaterium, in doses of one-twelfth of a grain, or less, to be repeated in a few hours, if necessary. The quantity is so small that it could readily be taken, and we know that it acts quickly and effectually in general or abdominal dropsies.

The opponents of the open treatment of the bowels fear increased peristalsis and the forcing of fæces, etc., in the peritoneal cavity, but when they recollect that perforation or extreme tympanites usually ends fatally, if not relieved surgically, the objection must fall to the ground. With the bowels thoroughly emptied at the onset of the disease, and the fact that the patient eats little or nothing, laxatives later can only carry off the flatus, which otherwise would escape through the perforation, or compress the lungs and heart, and most likely kill in either case. We use cathartics in the inflammatory intestinal disorders of infants, and in general inflammations elsewhere as a revulsive; then why not in peritonitis with effusion, whether septic or not.

Enemata are useful coadjutors of laxatives, but used alone they relieve but little the flatulence or inflammation in peritonitis. Glycerine enemata have been highly recommended of late, and, judging by the solvent and hydragogic effect of glycerine elsewhere, it should be an improvement on the old turpentine and soap injections. In leaving the subject of laxatives, I cannot do better

than quote from Dr. J. M. Baldy, of Philadelphia,[1] who first refers to the many bad effects of opium, and then says of laxatives: "The peritoneal cavity is drained of the products of inflammation; the inflamed surfaces are relieved of all engorgement by a thorough depletion of the vessels in the intestinal walls; the inflammation is most effectually stopped; the pulse and temperature almost immediately improve, and the pain is relieved as quickly as can be by the use of opium. This may seem strange, but it is a clinical fact."

From a study of this case, personal experience in other forms of peritonitis, and a review of much of the literature of the subject, the following conclusions are suggested:

1. That typhlitic diseases are intra-peritoneal, that in nearly every instance they originate in inflammation or perforation of the appendix or cæcum, usually caused by fæcal impaction or foreign bodies, that even though these diseases frequently do not primarily end in suppuration, still their tendency is to recur and eventually end fatally by septicæmia, or shock from ruptured abscess, or purulent peritonitis.

2. That, in view of the foregoing, all diseases of this region, giving symptoms of inflammation or peritonitis, without regard to the question of pus or abscess, and which do not yield promptly to the modern medicinal treatment and are progressive, should be treated by laparotomy at the earliest period possible.

3. That when peritoneal or intestinal adhesions or pus-sacs exist, they should always be broken up, the abdominal cavity thoroughly douched with sterilized plain water, at a temperature of 105° F., the wounds sutured, and the cavity drained by glass tubes.

4. That, excepting in undoubted cases of simple post-cæcal abscess unaccompanied by peritonitis, the incision should be made either vertically over the caput coli (after Sands), or, in the linea alba, below the umbilicus, and preferably the latter operation when extensive peritonitis or adhesions are suspected.

5. That, whether in operative cases or not, opiates should be used as little as possible; but, on the other hand, saline or vegetable cathartics (followed by enemata) should be used from time to time, to relieve the inflammation, tympanites, pain, and fever, and particularly to drain the peritoneal cavity of serous or purulent effusion.

131 West Forty-eighth Street.

Very Hot Compresses in Surgical Practice.—Professor I. I. Nasiloff gives an account of several cases of inflammation of the lymphatic glands which he treated with marked success by means of very hot compresses (*The Lancet*). These compresses consisted of a fourfold piece of linen, rather larger than the surface over the affected glands. It was dipped into water at a temperature nearly or quite equal to 212° F., wrung out, and applied quickly over the glands, its own temperature being then from 140° to 165° F. These applications were made morning and evening, the compress being allowed to remain on covered over with cotton-wool for about fifteen minutes. As may be supposed, the applications produced somewhat severe pain, but this did not last long, though sometimes not only redness, but a blister was caused. The treatment was continued for about a fortnight. It was found that it very soon began to promote absorption; this action was always accompanied by a rise of temperature, depending apparently upon the size of the diseased glands, and upon the extent to which absorption was taking place. It was noticed that the earlier the treatment was adopted the more effective it showed itself. Professor Nasiloff believes that hot compresses are a valuable form of treatment; not only in strumous glands, but in rheumatic osteo-myelitis and in fungoid inflammation of the joints.

URINARY CONCRETIONS IN CHILDREN.[1]

By J. HENRY FRUITNIGHT, A.M., M.D.,

Fellow of American Academy of Medicine, Fellow of New York Academy of Medicine, Secretary of Pædiatric Section of New York Academy of Medicine, etc.

Etiology.—Though urolithiasis may appear to be relatively an infrequent disease in childhood when compared with the whole number of children living, yet it is of special interest because the greater number by far of all the cases of this description is found among children. It is said that more than half of all the cases of calculus—and the vesical variety is the one especially meant—occur in childhood. Furthermore, when it occurs in children it is most frequent in those under five years of age. Nor are renal calculi so very infrequent in children, for the accumulation of uric acid in the kidney soon after birth may prevent the excretion of urine and may sometimes cause the formation of stones, which are occasionally found in very young infants. Thus Professor A. Jacobi has recorded that six times in forty post-mortem examinations of children under one year of age he has found renal calculi.

According to Roberts, of Manchester, England, of 1,827 persons who underwent lithotomy at various hospitals in England, 473 were under five years of age, and 528 were between five and fifteen years of age, hence more than fifty per cent. of these cases occurred before puberty. Dr. Geo. E. Post, of Beirût, Syria, has tabulated 176 cases of vesical calculus occurring in his practice, and 106 of these were in children under ten years of age.[2]

As in adults, calculi are more frequent in the male than in the female sex. Barthez and Rilliet cite eight hospital cases, of whom six were boys and two girls. Neubauer found but five girls in one hundred cases of the disease.[3] Giraldes asserts that vesical calculus happens twenty-four times more frequently in boys than in girls.[4]

Though the fact is well established that the disease is more prevalent in some regions of the world than in others, as in the warmer zones for instance, yet no portion of the globe seems to be totally exempt from its presence. The negro race, however, is claimed to be remarkably free from calculous disease.

It has been observed that those children in whom calculi are found usually belong to the humbler classes, just the reverse of what obtains in adult life. According to the writings of Sir Henry Thompson half of the cases admitted to Guy's Hospital for operation for stone are children of the poor. He states, too, that it is almost never found among the children of the more favored classes. This has been explained by the fact that in consequence of the coarse and indigestible food of which they partake, and which is chiefly amylaceous in character, the children of the lower classes suffer from malnutrition, which is favorable to the deposition of urinary sediments. As more care and attention are paid to the diet and nutrition of the children of the better classes this cause is not operative in them. The absence of milk as an article of diet is supposed by some to tend to the formation of stone.

Scrofulous and tubercular children have also been considered as predisposed to this affection, and in particular rachitic children are claimed to be remarkably prone to be affected. Of the eight cases of Barthez and Rilliet, already alluded to, four were afflicted with tuberculosis of the encephalon, and one with acute tuberculosis associated with pulmonary gangrene. Vesical calculus has also been announced as among the sequelæ of measles.[5]

[5] Coulson: Jahrbuch für Kinderheilkunde, No. 440, p. 34.

Heredity and family idiosyncrasy also seem to exert an influence in the occurrence of this disease, though by no means constant. A writer in the *London Lancet* for July 10, 1872, on page 204, reports a curious instance of this: "Six children of one family all had stone; the father and mother both passed quantities of uric acid, the grandfather and grandmother, a great-uncle, six uncles, four aunts, and one cousin had either all had attacks of gravel or were cut for stone."

Habits of life and nutrition play quite a prominent part in the causation of lithiasis. Habit naturally plays a more active part in adult life than in children, for the latter have not yet been confirmed in their habits, and it is therefore virtually without influence in early life.

Poor nutrition, already alluded to, favors the occurrence of lateritious deposits because of the abnormal composition of the urine under such circumstances.

The activity of the skin also enters as a factor of some influence in the production of urolithiasis; for the more active the skin is the more concentrated will the urine be, therefore the liability to calculus is increased because this liability stands in direct ratio to the amount of solid ingredients, and especially to the amount of uric acid which the urine contains.

The same general intrinsic causes are equally active in the child as in the adult. The concretion may be deposited in some one of the urinary organs from the unchanged urine because of some inherent vice in its composition. For instance, there may be present an excessive proportion of precipitable ingredients in the urine. The urine may be too acid in reaction, thus diminishing its solvent power over uric acid and the urates. A deficiency of the chloride of sodium and the alkaline phosphates also reduces its power of holding uric acid in solution. Again, an ammoniacal decomposition of the urine in the lower urinary passages is favorable to the precipitation of the earthy phosphates and carbonate of lime. Acid fermentation of the urine with the mucous secretions of the urinary passages assuming the rôle of the ferment, is another cause of urinary concretions. Occasionally children may have a catarrhal condition existing in the pelvis of the kidney which will favor the formation of uric-acid gravel, and which may also lead to symptoms which correspond exactly with those of calculus pyelitis of later life. If this catarrh of the pelvis of the kidney should last a long time it might gradually spread through the ureter to the mucous membrane of the bladder, and as vesical catarrh notably favors the formation of stone, vesical calculi might be developed.

The presence of an abnormal substance of slight solubility in the urine, as cystine or xanthine, predisposes to the formation of calculi. The accidental presence of a body suitable to become a nucleus for the crystallization of urinary sediments, as a clot of blood, inspissated mucous epithelium, etc., or a foreign body introduced from without, as a needle, a piece of wire, a bone, etc., will also give rise to the formation of concretions. I do not, however, know of any case among children which originated in consequence of the introduction of a foreign body from without.

That certain diatheses—as the rheumatic, gouty, or dartrous—exist in children, as in adults, favorable to the occurrence of these urinary deposits is to my mind problematical.

Pathology.—These concretions are most generally formed in the kidneys, whence they often pass into the bladder, where they increase in size and weight, and occasionally into the urethra. They are very seldom indeed formed in the urethra, but if found there they have been almost invariably arrested in their passage from the kidneys. They also may occasionally originate in the bladder. Urethral calculi occur especially in children. As has just been remarked, they are derived for the most part from the bladder or the kidneys, being calculous fragments which have been arrested at the narrowest part of the canal and lodging more especially at the bulbous portion or fossa navicularis. In some very rare instances the concretions may be formed in the urethra. Thus there may be a constriction in the canal behind which the urine may collect and deposit some of its salts—a nucleus is formed, usually of uric acid, and the evolution of a urethral calculus has begun. Again, the arrest of one or more gravelly particles may also give rise to the formation of urethral calculi. Dr. Fewsmith, in vol. xv. of *The American Journal of Obstetrics*, refers to a case of primary urethral calculus in a boy one month old which was apparently of intra-uterine growth.

Concretions may also form just within the prepuce, particularly if the latter be long and tight, and hence they are known as preputial calculi. These calculi may consist of inspissated smegma or of true urinary deposits. The latter variety may either have been formed here in a manner similar to what obtains when a urethral calculus develops *in situ*, or it may have escaped from the urethra into the preputial canal.

In newly born infants uric-acid infarctions are nearly always found in the kidneys. These are insignificant in extent, and they very rarely disturb the renal functions. The opinion which formerly prevailed, that these infarcts of uric acid were found exclusively in children who had breathed, has been demonstrated to be false. Indeed, they have been observed in the kidneys of still-born children, and even in those of the non-viable fœtus.

The presence of these infarctions in newly born infants is explained as being caused by an increased physiological tissue metamorphosis, which is induced after birth by the establishment of the processes of respiration, digestion, and calorification. These infarctions are rarest in those infants who die very soon after birth. They are more frequent in those children who have lived twenty-four hours, and most frequent in those who die between the second and fourteenth day after birth. Then until the end of the second month there is a steady diminution in the number of cases presenting specimens of these uric-acid infarctions, though Virchow has remarked their presence even in the period extending from the third to the fifth month of life. They are to be found, however, only in the minority of the kidneys of the newly-born. In fact, these infarctions are met with in less than fifty per cent. of the newly born infants, which proves that the conditions assuring their production must be inconstant. Concretions have also been detected in the kidneys in fœtal life. Langenbeck has discovered a calculus in the bladder of a six-months fœtus, demonstrating that they may be formed in intra-uterine life.

The calculi met with in children are most commonly composed of uric acid or the urates. Those consisting of the urates, and especially of the urate of ammonia, are most frequently found in nurslings. Ebstein denies the assertion that oxalic-acid concretions are more frequent in children than in adults. He refers to the case of a girl, seven years of age, who passed two large calculi whose kernels were uric acid, though their shells and middle layers consisted of oxalate of lime. If the urine be very concentrated, very hard uric-acid concretions will be produced by the depositions of concentric layers of that substance, and which may vary in color.

Cystine concretions are very rare in children, although Hodann removed a large one of this variety from a boy, six and a half years of age, by lithotomy. Xanthine and fibrine concretions, so far as I am aware, have not been observed in children; nor, according to Heller, have true phosphatic stones or the earthy phosphates been found in children. Carbonate-of-lime calculi, which are so extremely rare even in adults, have never been seen in children. When the concretions are formed in the urethra they are, as a rule, phosphatic in composition.

Renal calculi are usually few in number, but one or two being present. Of the vesical variety, one is generally found, but at times several may be present in that viscus. Erichsen says that he removed from a child, four years of age, a large conglomerate concretion formed of

eleven distinct uric-acid calculi matted together, besides which three others were found free in the bladder. Sometimes a calculus in the bladder is broken, and its fragments become nuclei for other calculi. In the bladder the calculi are generally loose, but they may become fixed by encystment in the sacculi of the vesical mucous membrane.

The size of these concretions in children ranges from that of a pea to a good-sized marble. Quite large calculi are often met with in very young female children.

The weight of a calculus does not depend so much upon its size as it does upon its chemical composition. It may weigh in children from a grain or two to a fraction of an ounce. Recently formed calculi are heavier than older ones, because they retain more moisture. Macnamara removed one weighing one quarter of an ounce from a child four years of age, which is unusually heavy for one removed from so young a patient.

The shape depends upon the structure and the composition of the concretion, though it is usually irregular. Vesical calculi are more ovoidal. When formed in the urethra they are elongated.

The color of a calculus, too, depends upon the chemical nature of the ingredients forming its enveloping crust. Calculi are also said to have a characteristic odor.

Their consistency varies from that of soft sand to that of hard marble, and depends upon their chemical composition, the amount of moisture present in them, and their molecular cohesion. Uric-acid calculi, which, as has already been stated, are the most frequent in children, are hard. In all varieties the outer shell is always the softer portion, while the nucleus is the denser.

Calculi when found singly are usually smooth, but when two or more are found together their surfaces may exhibit facets as a result of their attrition. Their mode of growth is seen in the consecutive deposition of the successive layers of which the concretions consist. I shall omit a description of the processes of chemical analysis of the various urinary concretions, because it does not strictly fall within the line of this paper.

Semeiology.—Though the uric-acid infarcts, which are so frequently present in the newly born, are usually washed away more or less speedily in the first month or two of life, some of the detritus may remain in the tubules and pelves of the kidneys, and by its presence an irritation will be produced which will cause disorder in micturition.

Infants undoubtedly suffer from nephritic colic as well as adults, though such a diagnosis is seldom made. The little one will suddenly become restless, it will then writhe in pain, all the time screaming wildly. After a while these symptoms will subside, and they are obviously relieved with every micturition. The same observations can be made in older children who have constantly recurring violent and apparently inexplicable screaming spells. These attacks depend frequently upon the presence and elimination of gravel and renal calculi.

The little patient suffering from urolithiasis will strain in its efforts to pass its water. There is intermittent urination accompanied by pain. In the intervals the sufferer is serene and undisturbed. In very young children if the napkin be examined it will exhibit dark reddish or yellowish stains, and occasionally gravelly crumbs can be felt. This brown dust is found oftener on the napkins of the puny infant than on those of the robust. The burning caused by the hyper-acidity of the urine is felt not only in the urethra but also at the meatus, the glans, and the labia.

In older children we have to deal more with newly formed concretions or gravel, rather than with infarcted uric acid. In such cases the discharge of urine is occasionally stopped entirely, and only a few drops are voided despite the most severe straining. In some cases retention may last from thirty-six to forty-eight hours with enormous distention of the bladder, extending sometimes even above the symphysis pubis, catheterization being necessary to relieve the patient. In other cases there is a constant trickling of urine from the urethra. The vicinity of the genitals is continually wet, and an odor of stale urine prevails. As a result inflammatory and œdematous conditions of the parts follow. If the urine of children, although clear when voided, lets fall a crystalline deposit before it has completely cooled, as is often seen, there is danger of the formation of a stone.

Older children fall into the habit of pulling and playing with the penis in consequence of the irritation of the disease, and in that manner attempt to relieve their distress. In these boys the prepuce becomes unusually long and developed.

In cases of vesical calculus the symptoms, it is true, depend somewhat upon the size and weight of the stone, but not absolutely. A sudden stoppage of the flow of urine occurs at times. Again, there may be increased frequency of micturition. Hæmaturia, though extremely rare in children, may be present. There is intense vesical tenesmus, with pain in the bladder and penis. The young suffer more from stone in the bladder than adults do. Priapism occasionally occurs. Frequent defecation accompanies stone in the bladder in children, in fact, fæces are often passed at every micturition. As a consequence of the severe straining in which the child indulges in order to pass water, prolapsus ani not infrequently occurs. There is a departure from the normal chemical composition of the urine. The following history illustrates what has been described:

Willie M——, aged two and one-half years, was brought to my office one morning complaining that his urine had suddenly stopped, and that now he could not pass any. I gave him a simple diuretic, but the symptoms of distention of the bladder increased, and I diagnosticated a stone in the bladder. I advised the mother to take the child at once to the hospital, where the diagnosis was confirmed, and on the following day the patient was subjected to median lithotomy, which resulted successfully in the cure of the disease.

If the stone lie loosely in the bladder, the child will, in order to escape its suffering and to pass its urine more easily, lie on the back or on the side, as the force of gravity will cause the stone to fall away from the neck of the bladder when such a position has been assumed. Sometimes, if the stone be free and small enough, and provided it assumes a proper position as regards the relative direction of its longest axis and the long axis of the urethra, the calculus may be expelled spontaneously. Such a case came under my notice last year.

E. S——, aged seven years, complained that at times, when he was urinating the flow would suddenly cease, which was accompanied by pain. Straining did not cause a return of the flow. After he had run about for a time the urine would again be voided. One day when he had retained his urine longer than usual, as he expressed it, "a longish white worm" passed from him. This body was undoubtedly a calculus, which was the diagnosis that had been made.

When the concretion is arrested in the urethra, which happens quite often in boys, the symptoms are mostly mechanical in their nature. Complete retention of urine always occurs. Œdematous swelling of the genitals then ensues. Frequently the calculi can be felt in the urethra by manipulation. Two cases of this description came under my observation within a short period of each other, whose histories I will briefly narrate.

Case I.—G. B——, at the age of two and one-half years, had had an obstruction to the flow of urine. He was examined by Professor Jacobi, who found a stone in the bladder which he removed by lithotomy. When the boy was nearly five years old I was called to see him because he could not pass his water. In examining him I detected under my fingers a hard body in the course of the urethra, about one-half inch behind the corona glandis, and which caused the boy pain when it was squeezed. He was placed

under ether, and by manipulation I was enabled to force it forward to a point within reach of the grasp of a long pair of dressing-forceps, with which the foreign body was extracted. It proved to be a urinary concretion.

Case II.—G. K——, aged three years, was passing water when suddenly the stream stopped and a whitish body partially protruded from the urethra. His parents were much alarmed and sent for me. The case was at once recognized as a urinary calculus impacted in the urethra. It was easily removed from the canal with an ordinary pair of dressing-forceps. Both children were then treated for urolithiasis for an extended period of time, and no more gravel or stones were developed.

If the stone be impacted in the deeper portions of the urethra very serious results often follow. For if the retention of urine be prolonged and relief be not quickly afforded, the irritation may eventuate in abscess, sinus, and urinary extravasation in the perineum, and finally incontinence of urine will succeed the irritability of the bladder.

Diagnosis.—The diagnosis of renal colic in infants is manifestly difficult. It is very likely that often when intestinal colic has been diagnosticated the child is really suffering from nephritic colic. Hence it is proper when a child is very restless and its actions denote pain to examine its napkins for the reddish-brown stain characteristic of urolithiasis. If dysuria be present the napkins should also be examined for the lithic sediment. If small concretions should be found in the diaper or in the urine of older children, it is advisable to explore the urethra and bladder of the anæsthetized patient. Every case of chronic dysuria, whether it be associated with vesical catarrh or not, should be thus examined in order to determine the presence or absence of calculi, as the exciting cause of this continued difficult and painful micturition. The predisposition to lithæmia is only detected after gravel or concretions have actually been found.

When the stream of urine is abruptly checked we may reasonably suspect the presence of a stone either in the bladder or in the deep urethra. But if we are in doubt the bladder should be examined in the usual manner with the sound in order to clinch the diagnosis.

Prolapsus ani in older children is a symptom which should not be undervalued for its indication of vesical calculus as a possible exciting cause. Priapism, too, in small children, should draw our attention to the possible presence of stone in the bladder. The presence of blood in the urine of children should certainly lead us to suspect the presence of calculous disease.

When called to a child suffering from retention of urine always suspect a concretion impacted in the urethra. For in boys the impaction of calculi in the urethra is almost the sole cause of urinary retention. In order to verify the diagnosis a physical examination of the perineum, and per rectum, should be made. Furthermore, in order to test the permeability of the urethral canal, it should be explored with a probe, and thus the diagnosis will be conclusively settled. Finally, error in diagnosis from lack of symptoms is not likely to occur, because in children these are generally more obvious than in the adult.

Prognosis.—The prognosis of this affection is much more favorable in childhood than in adult life. Simple gravel is nearly always cured. Still the uric-acid infarcts of infancy may occasionally be the first cause of a secondary nephritis, this disease being the result of actual irritation or real injury inflicted by the gravelly particles in the urine. The attacks of renal colic always end in recovery. Nor when concretions of appreciable size have formed are they *per se* necessarily fatal. Their direct results may, however, tend to unfavorable complications which will modify the prognosis in special cases.

The disease is more fatal in the male than in the female sex. Dr. William Roberts states that in the nine years from 1857 to 1866, in England and Wales, only 116 deaths among children occurred from calculous disease, which, it must be admitted, is a very small ratio. The rate of mortality of this disease among children is so low because they are usually seen early, and because proper measures of treatment can thereupon be instituted with more hope of success than later in life. Moreover, when operative procedures are resorted to, the prognosis is nearly uniformly favorable, for they are usually pre-eminently successful. Indeed, lithotomy in boys under the age of puberty is, perhaps, the most strikingly successful of all the great operations in surgery.

In regard to urethral calculi, it can be said that, if they are not located in the deeper portions, the prognosis is very favorable. If, however, they be seated near the bulbous portion, then the complications which may possibly attend them render the prognosis more grave, though not necessarily fatal.

Therapeusis.—The treatment of lithæmia in children is, as in adults, dietetic, medicinal, and surgical. In order to diminish the density of the urine, which, it will be remembered, encourages the lateritious deposits, and also to lessen the irritation of the kidneys, considerable quantities of water should be allowed. This recommendation applies as well to young infants as to older children. Parents generally do not seem to realize that the young child can become thirsty, and will require something to slake its thirst as well as older people, for we seldom meet with parents who give their infants water to drink. In older children other aqueous beverages and diluents may be permitted. Also, when from the previous voidance of concretions or gravel we are led to suspect a tendency to the formation of such deposits, we should, as a prophylactic measure, order copious drinking of fluids, the variety of which, whether alkaline or otherwise, must be determined by the chemical composition of the foregoing deposits.

The diet of older children should consist mainly of milk, the white meats, eggs, and farinaceous articles of food. Still the fear of azotized substances should not be carried too far in the regulation of the diet. Our object, in other words, should be to limit but not to restrict the ingestion of nitrogenous foods. Naturally the foods permitted must be easy of digestion.

Warm baths are to be recommended, because of the increased nutritive changes promoted by them. The bowels should be kept free. Whatever induces to an improvement in the general hygienic environment of the patient, including good air, food, clothing, etc., should be strongly insisted upon.

When acute paroxysms of nephritic colic attack infants and children they must be cut short by the exhibition, in sufficient doses, of the weaker preparations of opium, such as the camphorated tincture or papaver syrup.

Medicinal treatment should be directed toward the prevention of the formation of concretions when a tendency thereto is apparent, and toward the solution and consequent facility of expulsion of concretions which have already been formed. Hence it has been designated as the solvent treatment. The solvent treatment consists in the administration of alkalies or acids, according to the solubility of the deposits in alkalies or acids. In carrying out the solvent treatment, when the urine abounds in uric acid and its compounds, which is the usual condition in children, we must bring it up to a certain degree of alkalinity by the continuous administration of alkaline remedies, for these medicines are somewhat slow in their action. Among the alkaline remedies the acetate of potash and the citrate of potash are well thought of. The carbonate and citrate of lithia may also be given, likewise the carbonate of potash. All these medicines should be largely diluted with water in their administration, and the doses apportioned to the age of the patient. The phosphate of soda and ammonia, in doses of from gr. ij. ad gr. v. ter in die, according to age, has also been prescribed with benefit. The phosphate of soda—which also acts well on the bowels of children—benzoic acid, and the benzoate of soda may be given in the same doses.

Nor should the liquor potassæ be forgotten. The alkaline mineral waters, such as the natural Vichy, Bethesda, clysmic, Buffalo lithia, and others may also be recommended. The oxalate-of-lime concretions also demand an alkaline treatment. So long as the urine when voided continues sweet, the alkalies may be given, but should it become ammoniacal, then they must be discontinued lest a deposit of the earthy phosphates occur. The milder diaphoretics and diuretics can also be advised.

In phosphatic deposits the acid treatment is the proper one; but as these deposits are not met with in children its consideration will be dismissed with these few words.

In children these solvent remedies should always be administered per orem. Though vesical injections may be feasible in children, it seems to me that, inasmuch as we can obtain all desired therapeutic effects by the internal administration of the medicines, such injections should be discountenanced. Besides the direct action of these solvents upon the delicate mucous membrane of the child's bladder involves a certain amount of danger to it.

We may conclude, therefore, that the solvent treatment is applicable in cases of simple gravel, and in the early period of the formation of concretions, but that it ceases to be so when the urine becomes ammoniacal, and secondary deposits accumulate on the surface of the stone.

But when the stone, and the uric-acid variety in particular, is of considerable size, the solvent treatment by medicines will avail nothing, and recourse must then be had to the art of surgery. As a detailed description of the various resources which the science of surgery has developed for the cure and relief of these maladies is not embraced in the scope of this article, I will content myself with merely calling attention to certain salient conclusions, which are the outcome of the experience and observation of many distinguished and skilful surgeons.

Neither the operation of nephrotomy, for the removal of a calculus impacted in the kidney, nor the operation for the removal of one impacted in the ureter has ever, so far as I can learn, been done in the person of a child. The question of its feasibility I cannot discuss, but must submit it to the judgment of the surgeon.

In the past the operation of median lithotomy for vesical calculus was preferred for male children, as it gave the best results. For female children, dilatation of the urethra, with subsequent lithotrity, was the chosen mode of operation. Recently pulished reports, however, seem to show that the operation of litholapaxy is growing in favor as a promising operation for both male and female children, and it may in time supplant the two first-named operations for the majority of cases of vesical calculus.

When a concretion has become impacted in the urethra a gush of urine will sometimes force it out. If it remain fixed, the urethra should be dilated, and the offending body should then be extracted with proper forceps. If, however, the stone be of large size and deeply seated, an incision in the urethra may be necessary in order to facilitate its extraction. Care should be taken that it be not pushed back into the bladder. When the concretion has ulcerated through the urethra, incise the resulting abscess, remove the stone, and then treat the wound on general antiseptic surgical principles. The treatment of preputial calculi is so obvious that it does not need elucidation. Yet it may be proper to suggest the advisability of circumcision in certain cases of redundant prepuce, in order to prevent their formation.

161 West Fifty-seventh Street.

The Medical Society of Magdeburg has passed a resolution in honor of Drs. Gerhardt and v. Bergmann, "who so worthily upheld the glory and honor of German science" in their management of the case of the late Emperor Frederick.

Clinical Department.

A CASE OF MEASLES, FOLLOWED BY DEAFNESS, IN A DOG, CONTRACTED FROM THE HUMAN SUBJECT.

By JULIAN J. CHISOLM, M.D.,

Professor of Eye and Ear Diseases in the University of Maryland.

The extension of diseases from animals to man has been often noted, with cause and effect clearly traced. The reverse of the proposition is by no means so frequent, and hence, when a case has its chain of evidence apparently clear, it ought to be put on record. During the present course of lectures at the University of Maryland, one of the students, son of a well-known and highly esteemed practitioner, inquired of me whether deafness in a dog was curable, stating that a favorite setter dog had become deaf soon after an attack of measles, four years since, and had remained so, and that his usefulness as a hunting-dog was altogether destroyed through this infirmity. He told me that his father had recognized the acute disease at the time of its occurrence, and had called attention to the peculiar sickness in the dog before the hearing had become affected. Through this student I requested the father to give me the facts of the case, and obtained from him the following letter, which I think worthy of record:

"Federalsburg, Md., December 11, 1888.

"Dr. J. J. Chisolm:

"Dear Doctor: Some years ago my youngest son had a typical case of measles. Tasso, a favorite setter, was in the room with him most of the time. In about two weeks the dog began to cough, had inflammation of the eyes, fever, and thirst, all the usual symptoms of measles, except the rash. I regret I did not look under the hair for that. He was sick about the time it takes a case of measles to run its course in the human subject. The dog recovered its usual health, but with complete loss of hearing, which he has never regained.

"Yours truly,

"Charles W. Jefferson, M.D."

Littré on the Medical Calling.—Commenting on the Oath of Hippocrates, Littré wrote: "The medical profession is one of the most difficult which man can undertake. Grave responsibility, limited powers, obscurity in diverse cases, fleeting opportunity, the impossibility of retracing one's steps—all forbid him to play with the dangerous 'serpent of Epidaurus.' Add to this the personal risks inseparable from medical study and practice; add to this the incessant contact with suffering and death; add again the scientific training which strengthens and develops the mind; add once more the humane sentiments which direct the practice of an art essentially beneficent—and you will cease to be astonished that a profession so grave has, from a hoary antiquity, inspired a script so exalted in its character as the Oath of Hippocrates. But the Greeks—and this evokes our admiring wonder—the Greeks who, by being the first to introduce the physiological element into medicine which, up to their day, was empirical, have left so powerful an impress on its scientific future, have also been the first—for us denizens of the West at least—to give character to its moral future by formulating on the threshold the duties essential to its practice."

The Blood of Pneumonics.—Dr. Lucatello has observed, in examining the blood of pneumonics, that the serum is absolutely sterile, and he attributed this to the development of a toxic substance from the pathogenic micro-organisms.

Progress of Medical Science.

INTRALIGAMENTOUS TUBAL PREGNANCY; SUCCESSFUL REMOVAL BY ABDOMINAL SECTION OF A LIVING CHILD.—This case is reported by Dr. Joseph Eastman, of Indianapolis, Ind., who claims that no parallel case is on record (*American Journal of Obstetrics and Diseases of Women and Children*). Mrs. C——, aged thirty-nine, bore one child nineteen years ago. Suffered from frequent paroxysms of intense pain and rapidly increasing abdominal enlargement, since her flow stopped last Christmas. She was admitted to hospital on July 9th; operation, July 10th. Abdominal inspection and palpation showed tumor extending from near pubes upward, and to the right, reaching near liver. Conjoined manipulation disclosed uterus normal in size, well up between tumor and symphysis pubis. There was not less than three inches of fat between integument and tumor. Dr. Eastman failed to detect sound of fœtal heart. Breasts not enlarged. Very little discoloration around the nipple. Abdominal section revealed extra-uterine pregnancy, tubal variety. The tube seemed to have much of the right broad ligament surrounding its uterine attachment, as if the tube had been originally beneath the peritoneal fold of the broad ligament. The sac containing the child was a dark purple, and tore open easily on the touch of small forceps. Placenta was nearly under line of abdominal incision, yet the operator was enabled to open sac and extract child without detaching much of its tissue. Any manipulation of sac caused hemorrhage. He determined at once to remove tube and placenta in mass, and began by separating an adherent intestine and then an adherent omentum, being compelled to use pressure forceps and ligate five times before he reached and surrounded the tube with his fingers. By this time there was free hemorrhage from the margins of placenta and tube. He applied Eastman's clamp below the fingers around the neck of the sac, and found by this means he could so constrict as to arrest all bleeding; then cut off above clamp, and using No. 14 iron-dyed silk, quilted the pedicle (which the clamp had made for him) with cobbler's stitch. He washed out the peritoneal cavity with pure water (temperature, 105°) three times, put in glass drainage-tube, and closed wound with silk-worm gut, and found to his great satisfaction that the patient had suffered little shock. Her highest temperature was 102°. Bowels moved on third day, and drainage-tube was removed on fifth day.

The only similar case which he has been able to find is the following, from the *Am. Jour. of the Med. Sciences*, February, 1888. The two cases referred to by J. G. Smith (second edition "Abdominal Surgery") are *not* parallel. In Jessup's case, no tube was removed, and in Martin's case, while the tube was removed, the child was moribund. "At a meeting of the Society of Physicians of Vienna, Breisky reported the case of a woman, aged thirty, who had given birth to a living child six years previous to her extra-uterine conception. She suffered from peritonitis after confinement, and had never been free from pelvic pains. Extra-uterine conception was followed by chronic peritonitis; fœtal movements were perceived at five months, when the pains lessened. Breisky diagnosed intraligamentous tubal pregnancy. On examination by palpation, the uterus could be felt, lying in front of the tumor. By vaginal examination the true pelvis was found to be empty, the vagina drawn toward the left. The tumor was at the right of the uterus, the fœtal parts could be outlined, and the heart-sounds heard. The operation was performed at the end of eight months of pregnancy. After a central incision, the fœtal sac presented in the wound; it was stitched to the abdominal wall by four sutures; at its thinnest point an opening was made and the child was rapidly extracted. It weighed over five pounds, was asphyxiated, but was promptly resuscitated. The four fixation-sutures were then removed; the sac was drawn out, ligated at its junction with the uterus, and removed. Externally the adhesions were but partially broken up, as the sac was adherent to the intestines and omentum. The sac, placenta, and membranes were removed, and the wound drained and sutured. The mother recovered perfectly in three weeks. The sac presented a considerable development of muscular tissue, and seemed mostly developed from the serosa; the placenta was large, and showed adherent lobules. Three weeks after delivery the child died from inflammation of the umbilical vein—a termination not to be ascribed to the operation. Breisky claims that this is the first case of the successful removal of the living fœtus, with all its appendages, in extra-uterine pregnancy. From the consideration of three cases previously operated upon by him, Breisky believes that in advanced cases of extra-uterine pregnancy, when the fœtus lives, we should extirpate the entire sac. To await the formation of a lithopedion is not admissible, as perforation of the bladder or intestine, or septic infection may result."

Under date of January 14, 1889, Dr. Eastman writes that the mother and child remain in perfect health. This case is, therefore, probably unique.

THE RELATION OF ACETONURIA TO DIABETIC COMA.—At a recent meeting of the Royal Medical and Chirurgical Society (*The Lancet*, December 1, 1888) Dr. Samuel West read a paper on this subject. The relation of acetonuria to diabetic coma had been investigated by experiment and by clinical observation, and this paper was a contribution to the clinical side of the problem. The results of experiment were briefly referred to, and the conclusion to which they led. Clinical observation was for a long time difficult from the want of trustworthy tests. A short account of the chief ones was given: 1. Lieben's iodoform test. 2. Gunning's and Le Nobel's modification of it. 3. Reynolds' test. 4. Legal's test with nitro-prusside of potassium. 5. Le Nobel's modification of it. 6. Penzold's test. Legal's test was found to be the most convenient for use in the urine direct, and Lieben's in the distillate, but this reaction was also obtained if alcohol was present. But if the urine gave Legal's, and the distillate both Legal's and Lieben's tests, the presence of acetone might be accepted. As control experiments two series of convalescent cases were examined. In the first thirty cases, a doubtful Legal's reaction was obtained in three. In the only one which was distilled neither test was obtained in the distillate. In the second series of about the same number no evidence of the acetone was obtained in any. Of non-diabetic patients actually suffering from illnesses at the time of examination, acetone was found in fifteen cases. Acetonuria was therefore very rare in healthy or convalescent persons, but common in various forms of acute and chronic disease. Of diabetic patients fourteen were examined, four being at the time comatose. In some of these cases the examination was continued for many days. The following conclusions were arrived at: 1. Acetonuria was common in diabetics without coma. 2. It was not constantly present in cases of diabetic coma. 3. It varied greatly in the same case from time to time without definite cause. 4. It varied independently of variations in the amount of sugar, specific gravity, etc. 5. It might even disappear when coma developed. The iron reaction showed also no relation either to coma or to acetone. Experiment and clinical observation therefore led to the same conclusion—viz., that acetone could not be the cause of diabetic coma. Clinical observation, however, seemed to show that acetonuria had a clinical value as indicating that the patient was in a more critical condition than when it was absent. The symptoms of diabetic coma depended, in all probability, upon acute intoxication by some substance rapidly generated within the body, but at present unknown. It might be that in the perverted chemical processes which developed it, acetone and the allied body giving the iron reaction were pro-

duced, so that the presence of these bodies in the urine might serve as "danger signals." In discussing this paper Dr. Maguire said that acetone was evidently not the poison which produced diabetic coma; nevertheless, the condition was undoubtedly due to the presence of a poison. The liver either might split it up or the kidneys eliminate it, so that, although it might be found in the blood, serious symptoms might not develop. He looked upon the presence of albuminuria as a valuable danger signal when occurring in the course of diabetic coma, its presence being probably due to renal irritation. In every case he had examined the kidneys had presented extreme parenchymatous inflammation, and such a condition could be brought about by the injection of diacetic ether or acetone into the blood. He thought that, if albumen were found after acetone had been ascertained to be present, the case was graver than if acetone were found alone.

THE THERAPY OF TABES DORSALIS.—Stembo (*Berliner klinische Wochenschrift*, October 29, 1888) says that though so much is written concerning tabes, yet but little appears as to its treatment. This is because it is so generally considered to be beyond the reach of treatment, though many well-known writers have shown that at least some cases prove that it is not incurable. The author has had under his care thirty-nine cases of tabes in the last few years, and has reached the conclusion that the sooner treatment can be begun the better result may be expected. Syphilis is certainly a prediposing, if not a proximate, cause of tabes, and yet this fact seems to be of little value in the therapeutics of the disease. Twenty-four of the thirty-nine cases were distinctly syphilitic, but not one of them was benefited by antisyphilitic treatment. Iodide of potash has never helped his tabetic cases, and he has likewise obtained no good results from arsenic, belladonna, ergot, and strychnine. He has found antifebrin in full doses very serviceable in relieving pain, and decidedly superior to both antipyrin and phenacetin. Cocaine was often useful in gastric crises. Great difference of opinion exists as to the value of hydrotherapy, and what form of it is to be employed. The author believes that the bathing resorts with warm baths are preferable in the early stages, especially when the patients are anæmic and weakly. In the more advanced states, in strong individuals, in whom an increased blood-supply is desired, the cold-water cure may be tried. Care must be used, however, that it is not overdone, and cold sea-baths especially must be given with the greatest caution. Electricity is by all means the best treatment for tabes, yet it must be employed with precision, and not by the patients themselves. The constant current has been the one chiefly employed in Germany, England, and Russia, while the interrupted current is also used in France and America. Carefully describing his methods of applying it, the author says that he uses in some cases the constant current applied to the back, followed by the faradic current, or by franklinic electricity applied to the same locality. In other cases he employs the galvanic and faradic currents simultaneously, in the manner described by De Watteville. He reports three cases as examples of the surprising improvement which can follow electrical treatment.—*The American Journal of the Medical Sciences*, January, 1889.

THE PREVENTION OF TYPHOID FEVER.—Dr. Reed has formulated (*Sanitary News*) the following conclusions relating to typhoid fever: 1. Typhoid fever is caused by the introduction of a specific germ into the alimentary canal. 2. This specific germ multiplies in the alimentary canal, and in turn is thrown off in the stools of the patient. 3. Its vitality is much greater than at first supposed, resisting a variation of temperature ranging from even below the freezing point to 133° F. 4. The germ may be communicated from one person to another, by water, milk, foods, and air. 5. To prevent its spread, all the dejecta should either be burned at once (which is preferable), or thoroughly disinfected, by throwing them into a pot of boiling water and thoroughly cooking them, or using some effective germicide, such as a strong solution of the bichloride of mercury in sufficient quantities to insure their destruction before they are buried, which should be at a sufficient distance from any neighboring water-supplies to insure their freedom from contamination. 6. If the water-supply is of a suspicious character, thoroughly boil it before using, and then place it where there is no possibility of its becoming infected. If ice is used, pack it around the water-vessel, not allowing the melted ice in any way to enter your drinking-water.

OÖPHORALGIA TREATED BY INTRA-UTERINE FARADIZATION.—In the experience of Dr. Everard, of Mons, this affection is usually accompanied by what are considered hysterical symptoms (*The Lancet*). The patients are as a rule young girls, and they complain generally of violent and frequent headaches, buzzing in the ears, exaggeration of the olfactory and gustatory senses, ocular troubles, loss of memory of words, anæsthesia and hyperæsthesia of different parts of the body, capricious appetite, bad digestion, irregular bowels, and cough more or less frequent, for which no reason can be found on examination of the chest. The treatment hitherto has been chiefly symptomatic, and has not been very successful. Dr. Everard has of late, however, employed Apostoli's method. He uses a bichromate of potash faradization apparatus, to which is connected an Apostoli's bipolar rheophore containing the two currents, which are separated by a thin piece of gutta-percha. This sound is introduced either into the vaginal fornix or into the uterus itself. The coil is so arranged as to supply currents predominating in tension or in quantity at will. Care must be taken to increase the strength very gradually, and to diminish it the moment the patient complains of pain. The greatest cleanliness is required, antiseptic injections being used before and after the sitting. Dr. Everard gives some cases where some half-dozen faradizations produced a great change for the better in hysterical patients with enlarged and tender ovaries.

A NEW OPERATION FOR TORTICOLLIS.—Dr. Levrat has devised a new method of treating torticollis. Instead of operating subcutaneously, he cuts down upon the sternal tendon of the sterno-mastoid muscle, effected by a longitudinal incision two centimetres long. He clears the tendon with the forceps, passes a grooved director under it, and divides it. He then divides any tissue that may bind down the muscle at that spot, sutures the wound, and dresses it antiseptically with iodoform and gauze. Over the dressings he places the following apparatus: The head being enveloped in cotton wool, a silicated bandage is wound horizontally around it at the level of the forehead, and a similar bandage vertically over the crown and under the jaw. Where these bandages meet at the level of the mastoid process on the sound side, a small hook, with the concavity looking upward, is inserted. Another silicated bandage is wound round the body below the axillæ, and through the thickness of the bandage a hook is inserted in the middle line in front, having its concavity looking downward. When the bandages have dried, the two hooks are connected by a band of india-rubber, which assists the sterno-mastoid of the sound side to keep up a continuous traction and so correct the deformity. This apparatus and the dressings are left untouched for fifteen days, and the success of the operation is said to be assured.—*The Lancet.*

SWEATING OF THE FEET.—Dr. John Morgan writes: "By applying boric acid thoroughly to the feet, particularly about the nails, between and under the toes, and to the soles, two or three times a week, or oftener, as the case may be, dressing them while there is a good coating of powder on the skin, sweating of the feet may be effectually relieved. The application is easily made and will prove very satisfactory." Washing before and after might help!

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 2, 1889.

THE MEDICINAL TREATMENT OF MENSTRUAL DISORDERS.

THE treatment of symptoms alone, without regard to the underlying condition, of which the symptoms are but the expression, is often looked upon as unscientific and unworthy of the consideration of the true physician. It is, indeed, unscientific, and were it possible always to discover and remove the cause it would be equally irrational and unjustifiable. But unfortunately we are unable always to act upon this principle. We cannot always discover the cause, and, knowing or suspecting it, we are often unable to remove it. This is noticeably so in regard to menstrual irregularities, especially as occurring in young women. The general practitioner is often asked to relieve cases of this nature in girls who would never submit to an examination or operation, preferring rather to suffer pain indefinitely than the shame of a physical investigation into the nature of their trouble. In such cases the physician is forced to try the effect of medicinal agents, groping, it may be, in the dark, before insisting upon an examination. Such being the case, it is well to learn what remedies have been found to be of occasional service in relieving symptoms of this nature which are not dependent upon actual organic disease.

In a very practical paper, read before the Connecticut Medical Society at its annual meeting in 1888, Dr. Gideon C. Segur, of Hartford, presents a general review of the subject, giving the results of his own experience and quoting the opinions of several prominent gynecologists whom he has consulted. A brief *résumé* of these opinions is all that can be presented here, the reader who may desire a more extended presentation of the subject being referred to the orginal paper.

Amenorrhœa.—For this condition most of the authorities consulted recommended general tonics, iron, arsenic, and cod-liver oil. Permanganate of potassium, which was at one time so strongly recommended, does not seem to be in much favor, the objection to it being that it is too irritating to the stomach. Manganese was advised by some, and this is the remedy that the author has found to give the most satisfactory results. Most of the salts of this drug, however, cause so much gastric irritation that they cannot be used in most cases, but the binoxide seems to be an exception in this respect, Dr. Segur having used it in many cases with the happiest results and without seeing any disagreeable effects caused by it. A disagreeable feature of this remedy, in Dr. Mundé's experience, though apparently not in the author's, was its unreliability. It might afford relief at one time, and yet at another, even in the same case, and seemingly under the same conditions, it would fail utterly to bring on the menstrual flow. The lactate of manganese is also free from the irritating action upon the stomach that most of the other salts of the drug exert. Manganese has the reputation of being an abortifacient, hence some caution is necessary in its use as an emmenagogue. But the maximum dose employed by the author is six granis a day, and this is far below that which has been used to produce abortion.

Dysmenorrhœa.—The opinions of the authorities consulted by the author concerning this symptom and its relief were most varied. Some thought no benefit could be obtained by any but operative measures, while others spoke hopefully of many remedies. Among those which seemed to have given most satisfaction to the writers were pulsatilla in three- to five-drop doses three times a day; cannabis indica, viburnum, camphor, belladonna, and antipyrine. Dr. Segur found manganese to render good service in these cases also, in many instances. The binoxide was used in doses of six grains per diem. The application of heat, by means of the sitz bath or douche, was a useful adjuvant to the internal medication.

Menorrhagia.—For this condition the most efficient remedies were found to be ergot, hydrastis, digitalis, sulphuric acid, fluid extract of gossypium, and gallic acid.

It is rather strange to find such a want of unanimity in the recommendations of these different authorities concerning the most efficacious medicinal agents for the relief of menstrual disorders. It is rather discouraging, also, as the number of remedies vaunted as useful in any particular trouble is generally in inverse proportion to its amenability to treatment. Yet, notwithstanding the discouragements which those who attempt to treat menstrual disorders by drugs often encounter, the physician is many times powerless to treat them in any other way. Dr. Segur has, therefore, rendered good service in collecting the opinions of so many experienced gynecologists, and in giving the results of his own efforts to relieve sufferers of this class, and we hope that the paper will be useful to many who may perhaps be able occasionally to cure some of these disorders by one or other of the remedies mentioned by the author.

PROPOSED PUBLIC BOTANIC GARDEN IN NEW YORK.

THE Torrey Botanic Club, of this city, has recently sent out an "appeal for a public botanic garden in New York City," which commends itself—not only especially to the class whom they hope to interest—but to all good citizens. The amount of money required to establish and maintain a botanic garden is so large that the members of the club have very wisely realized that the possibility of receiving such a fund by subscriptions of small amounts from the general public is too slight for consideration. From the earliest times botanic gardens have originated almost wholly from the public spirit of wealthy individuals, as, for instance, that of Matthæus Sylvaticus, at Salerno, in 1309; the one established in Padua, by a wealthy Tuscan nobleman; the public botanic garden of Leipzig, founded by the elector of Saxony, in 1580; the

one at Oxford, established by the Earl of Danby, in 1632; and the private botanic garden of Dr. Balfour, established in Edinburgh, about 1680, and subsequently assumed and carried on at the expense of the University.

The various governments of Europe have long taken an interest in the establishing and conducting of botanic gardens, beginning, perhaps, with the one established by Venice, in 1333; the celebrated Jardin des Plantes, in Paris, founded by Louis XIII., in 1610; the noted Kew Gardens, under the care of the Britith government; the Botanic Gardens at Berlin, and numerous others, all of which have rendered decided service, especially to the medical sciences, in the acclimatization of useful plants and fruits, and have been an unending source of interest and education to the people. The number of educational institutions, colleges, universities, libraries, hospitals, etc., which have been endowed, during the past quarter of a century, by the wealthy men of America, is very large; and the possessor of large means, who would confer a benefit upon his country and erect a monument for himself, by devoting a suitable endowment to some public service, must find his range of choice much limited, and the suggestion is not untimely made that, in the direction of a public Botanic Garden, a new and most useful benefaction may be conferred. The appeal issued by the Torrey Botanical Club tersely states several special uses of a botanic garden. That especially one which is interesting to the medical profssion is as follows:

"Students in medicine and pharmacy approach the study of botany with a particular object in view. Plants of medicinal value have for them a special importance. With ample means at command, it would be easy to obtain an abundant representation of plants of this nature, without prejudice to the purely scientific character of the garden, thus securing for the institution the highest degree of pharmaceutic usefulness, and making it a valuable auxiliary to our medical schools."

It is in this connection that we particularly desire to commend it to our readers. It is not desired by the Torrey Club that their appeal should be considered in the sense of a specific request for money, but rather of the presentation of an opportunity for a man of wealth to do himself an honor, and at the same time a great and lasting service to the public and to the cause of science. But few members of the medical profession are financially able to render themselves immortal in this way, but from the nature of their relations to their patients they are, perhaps, in a better position than most to suggest to some wealthy friend or patient the unique opportunity this scheme for a botanic garden in the city of New York presents.

Copies of the address may be obtained from Mr. E. E. Stern, 23 Union Square, who will also furnish any further information that may be desired.

ANOTHER CAPITAL OPERATION MADE SAFE.

IN 1864 Professor Gross referred to the operation for extirpation of goitre as "horrid butchery." Up to that time the mortality from the operation was over forty per cent. In the century from 1771 to 1875 the mortality, according to Welch, was 25.48 per cent. In the third quarter of the present century, 1850 to 1877, the mortality fell to 19.4. In 1882 the average mortality was 13.9 per cent., though in the next year Liebrecht published a table showing a reduction of mortality to 8.3 per cent.

Professor Theodor Kocher, of Bern, in his first series of fifty-eight operations, published in 1882, reported a mortality of 14.8 per cent. Two years later he reported forty-three more cases, with a mortality of 6.9 per cent. Five years later, that is to say in the present year, Kocher reports a list of two hundred and fifty more goitre extirpations with only six deaths, giving a mortality rate of only 2.4 per cent. Of these cases twenty were for malignant disease, and here the mortality was fifteen per cent. (three deaths). Of five cases of Basedow's disease, one died. Leaving out these cases, and including only simple goitrous enlargements, the mortality is reduced to two, or 0.8 per cent. One of the cases died from ether, and the other was moribund when the operation began, so that Kocher now claims that the operation for non-malignant goitre is free from danger, and can be safely done even for a cosmetic effect alone. Kocher's results add another to the long list of triumphs of modern surgery.

It is not to be forgotten, however, that such a low rate of mortality does not represent as yet the results of surgery in general. It is a special achievement that has followed upon the natural skill and extraordinary opportunities of Kocher. There will come a time, however, when most good surgeons can get nearly the same results as those attained at Bern.

DEFEND YOURSELVES FROM TYPHOID FEVER.

UNDER this title Professor Carlo Ruata, of Perugia, gives a striking account of the prevalence of typhoid fever in Italy. Every year, he says, this disease attacks from two hundred thousand to three hundred thousand individuals, and causes a mortality of twenty-seven thousand seven hundred. One-third of the persons in Italy who reach the age of forty-five are attacked with typhoid fever. In several districts over three per cent. of the inhabitants die from the disease annually.

The extraordinary prevalence of typhoid fever in Italy can be better realized by a comparison with the rate in this country. Massachusetts, with a population of two millions, has annually less than one thousand deaths from typhoid fever. Italy, with a population fourteen times as great, has twenty-seven times more deaths from this disease.

It is inexcusable that civilized states at the present day should allow a disease relatively so controllable to make devastations such as those in Italy. Well may Professor Ruata exclaim, "Defend yourselves from typhoid fever."

THE GROWTH OF ATHLETICS.

THERE is no more favorable sign of the times than the growing popularity of athletics. As the nation grows more wealthy, and luxurious habits develop, invalidism tends to increase. This is offset in a measure by our better knowledge of how to live and how to train the rising generations. No amount of physical culture can take the place of regular habits and temperate living; but it can do a great deal in showing how the delicate can be made robust, and how much more enjoyable existence is

when one has firm muscles, good digestion, and a clear brain.

Dr. W. G. Anderson, of Brooklyn, in a recent lecture has given some figures showing the amount of money that has been spent, mostly in the last few years, on athletics and gymnasiums in this country.

The colleges, he says, have spent $750,000 in facilities for the instruction of gymnastics; the preparatory schools, $250,000; the athletic associations in this city and vicinity, quite $750,000; the German Turnvereins, $2,500,000, and the Young Men's Christian Associations nearly as great a sum.

We are still, however, much behind European nations. Berlin, in 1881, had 70 gymnasiums, which cost $50,000 to maintain; Frankfort spent $27,000 a year on 18,000 children; Vienna, $34,000 for 135 schools, with 72,000 scholars. In Prussia the gymnasium was used by one-fifth of the population.

Dr. Anderson gives a hint to young physicians by saying that the services of a physician who was also a good gymnast were at a premium in hundreds of schools and colleges throughout the country, where they might receive salaries far in excess of any probable earnings in their profession.

News of the Week.

Dr. Daniel L. Everitt was found dead in bed at his residence in Brooklyn, on the morning of January 25th. He had been suffering from rheumatism in his chest for some time, and it is supposed endocarditis ensued. Dr. Everitt was sixty-six years of age, and a native of Modena, N. Y.

Death of Dr. Charles Bliss.—To the long list of sudden deaths in our profession another was added last week. While going down cellar the stairs collapsed, and Dr. Bliss fell to the floor, striking his head. Though not unconscious at first, he speedily became so, and died within an hour. Dr. Bliss was a native of Lee, Mass., and was forty-eight years of age. At the outbreak of the rebellion he enlisted in the cavalry. He was honorably discharged before the war terminated, and began the study of medicine. He was graduated at the Berkshire Medical College in Pittsfield, Mass., in 1865, and, coming to this city, became associated with Dr. N. C. Husted. Dr. Bliss met with success as a physician, and accumulated a large fortune. He was a member of the County Medical Society, the Society for the Relief of Widows and Orphans of Medical Men, a Mason of high degree, and an officer in the Order of Foresters.

Dr. John W. Underhill, of Cincinnati, died last Monday from the effects, it is said, of cocaine. A few years ago he began experimenting with the drug, and became a hopeless victim, although he was a man in fine health and a physician of excellent standing.

The Largest Medical Society in Germany is the Berliner Medicinischer Gesellschaft, which now has seven hundred and thirty-six members. At its recent annual meeting, on January 9th, Professor Virchow announced that the New York Medical Society had contributed the sum of 1,000 marks to the Langenbeck memorial fund.

Dr. Franz Steinhausen, a well-known German physician of Utica, died on January 28th, aged fifty-three years.

The Eighth German Congress for Internal Medicine meets at Wiesbaden on April 18th, under the presidency of Professor Liebermeister.

Medical Missionaries.—The Rev. Dr. Taylor, of the Broadway Tabernacle, preached last Sunday on the subject of medical missions, with special reference to the International Medical Missionary Society of this city. He warmly commended the work of the International Society, established in 1881 by Dr. Dow Kontt. It had grown from a dispensary in the Fourth Ward to seven in this city and Brooklyn. Nearly 70,000 attendances have been given to sick poor, and sixty students were trained last year.

The Supreme Court on the Question of the Regulation of Medical Practice by the State.—An important decision has been rendered by the Supreme Court of the United States, supporting the right, claimed by the State Board of Health of West Virginia, to make rules for the regulation of the practice of medicine. The statutes of that State enact that every practitioner must qualify himself for legal practice by obtaining from the Board a certificate that he is a graduate of a reputable medical college, or has been ten years in the State engaged in practice, or that he has passed a satisfactory examination before the Board. A practitioner named F. M. Dent, having been convicted of illegal practice, carried the case up to the State Court of Appeals, and thence to the United States Supreme Court, asserting that the law was unconstitutional, inasmuch as it deprived him of liberty and property without due process of law.—*Medical News.*

A State Board of Health for Florida.—The Governor of Florida has called an extra session of the State Legislature for the purpose of establishing a State Board of Health.

The Bacillus of Yellow Fever.—In a pamphlet embodying his remarks on the etiology of yellow fever, made before the Association of American Physicians, Dr. Sternberg shows that bacilli claimed to be germs of yellow fever are in reality identical with the bacillus of Emmerich, and the bacterium coli commune of Escherich. These are micro-organisms found in healthy intestines.

The Alabama Medical and Surgical Age, is the title of a new monthly published in Anniston, Ala., and edited by Dr. John C. Le Grand.

Les Archives de Médecine Expérimentale et d'Anatomie Pathologique is the title of a new journal, to appear bi-monthly, and edited by MM. Charcot, Grancher, Lépine, Straus, and Joffroy. It is to cover about the same ground in original work as Virchow's Archives.

Child-labor.—Mrs. Amelie Rives-Chanler is reported to have offered a prize of $100 for the best essay on child-labor.

Whooping-cough.—Dr. Guerra Y. Estape, according to the *New Orleans Medical and Surgical Journal*, December, 1888, regards the local application to the larynx and pharynx of a ten per cent. solution of resorcin as the best treatment of whooping-cough at present known.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.—We remind our New York State readers that the State Society meeting will be held at Albany, commencing February 5th. A large number of papers are already promised, and special arrangements have been made for their reading and discussion by assigning them to medical and surgical sections. The fare, as already announced, has been reduced via Hudson River Railroad.

NEW YORK CANCER HOSPITAL.—There is a vacancy on the house staff of this hospital. The term of service is one year. Time begins December 1, 1888, and to one going in now could be dated back if desired. The service is large and of increasing interest, including all forms of cancer in women. Apply to Dr. James B. Hunter, 2 East Thirty-third Street, for particulars.

THE PROTECTION OF AMERICAN PHYSICIANS.—A correspondent of our virile and patriotic contemporary *America*, writes to that journal regarding the subject of "Discrimination against American Doctors." He says: "Nine-tenths of all the quacks and charlatans in this country are foreigners. They bring with them certain papers which are called diplomas. Some of them are granted by institutions which would not be recognized if existing here, but such is the reverence which certain Americans have for any foreign parchment that these diplomas are received without question." Quoting Dr. Meany in the *Inter-Ocean*, he adds: "In concluding, I beg to say, a diploma from no matter what medical college in the United States is not recognized in England; whereas, any qualification from England, in nearly all the States of America, appears to be sufficient to entitle the holder to practise medicine, surgery, midwifery, etc., without an examination of the branches of medicine or surgery he failed to pass upon in England, and without a qualification so to practise."

LEPROSY IN NEW YORK.—A correspondent asks if there are any cases of leprosy in New York. We would say that we know of at least one case. Some time ago there were a few cases in the public hospitals, and probably these are still in the city.

THE VIRGINIA MEDICAL EXAMINING BOARD AND THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.—Dr. Peter D. Keyser, Dean of the Faculty of the Medico-chirurgical College, writes us regarding the report copied in our columns, that three graduates of that College came before the Virginia Board and all failed. Dr. Keyser says that, instead of three persons going before this Board there was only one, and he went up three times. This gentleman passed a good examination before the Faculty, receiving an average of 85.05 out of a possible 100, the minimum mark of those allowed to pass being 70. Dr. Keyser sends us a copy of some of the examination papers which were submitted to the young man in question. These show that the standard required of graduates is a good one.

WAR TO THE KNIFE.—The quiet valley of the Ohio, the whilom home of Aaron Burr, has been surprised by a challenge. This is issued by Dr. R. Stansbury Sutton, of Pittsburg, to Dr. E. S. McKee, of Cincinnati. Dr. McKee made a visit to Paris, and returned an apostle of Apostoli, the father of the treatment of fibroid tumors of the uterus by electricity in strong and accurately measured doses. On several occasions since his return he has written concerning this subject, and, at a recent meeting of the Cincinnati Academy of Medicine, spoke of it as an "efficient substitute for the knife, which has been so generally feared in cases of fibroid tumors of the uterus." Dr. Sutton, who has a private hospital and belongs to the Tait school of gynæcologists, bitterly opposes this method, and publishes a challenge to Dr. McKee, in which he offers to furnish him with three patients suffering from fibroid tumors of the uterus, furnish all the apparatus necessary, and support Dr. McKee and the three patients in his private hospital, and for each tumor removed give the doctor $1,000; time limited to one year. In case of failure Dr. McKee is to be the loser. Dr. McKee accepts the challenge, provided all the conditions remain the same, except that the contest take place in Cincinnati instead of Pittsburg, not feeling justified in relinquishing his practice for six months or a year for the inducements offered.

PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.—S. Weir Mitchell, M.D., LL.D., has been elected Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic and College for Graduates in Medicine, an additional chair upon that subject being created.

THE MORALITY OF CANNIBALISM.—A writer in the *Fortnightly Review* denies the immorality of cannibalism, and thinks that a good way to dispose of the defective, aged, and dependent classes would be to eat them. The expense of burial would not only be saved, but there would be an immediate and important contribution to our food-supply. This idea was fully set forth by an American writer some years ago, who showed that cannibals were, as a rule, a high type of the savage, and that their diet had a scientific and economic basis of justification.

SLEEPING IN CLOSED ROOMS.—A Buffalo physician, in discussing the subject of "colds," has lent the weight of a medical name to the view that people should sleep with closed windows when the external temperature is below 65° F. Such advice is calculated to do much harm. While no one now advocates the practice of sleeping in very cold rooms, there is no doubt that much discomfort and ill-health would result from sleeping in rooms having no direct communication with the outside air.

ARSENIC IN THE HOME.—Mr. A. W. Stokes (*London Chemical News*) has examined a hundred samples of imitation Indian muslins and cretonnes. He found that twenty-three per cent. contained arsenic in appreciable quantities. The highest proportion, 2.1 grains of white arsenic per square yard. The colors in which arsenic was principally present were the terra-cotta reds and the greenish-browns. Of the wall-papers submitted to Mr. Stokes by various manufacturers, ten per cent. were found to contain arsenic. Thirty other articles of household use, such as plushes, velvets, carpets, mats, silks, etc., were examined, and in only one sample—a little flax mat of green color—was arsenic found.

A STERILIZING INSTITUTE has been established at Vienna. It has no gynæcological wards, however, and its object is to sterilize milk, not women or men.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, January 15, 1889.

R. C. M. PAGE, M.D., CHAIRMAN.

ELECTION OF OFFICERS.

DR. R. C. M. PAGE was elected Chairman, and DR. G. R. ELLIOTT, Secretary, for the ensuing year.

DR. SCHUMAN LECLERCQ, of Carlsbad, Austria, read a paper (see p. 113) on

THE INFLUENCE OF CARLSBAD WATER ON URIC ACID EXCRETION.

DR. FESSENDEN N. OTIS said he had listened with great pleasure and interest to the scientific researches concerning Carlsbad water recorded in the paper, and that he rose more particularly to say something of his own impressions concerning its therapeutic value as gained from a course of treatment in his own person at Carlsbad during the past summer, from his observations of the effect of the water on the different classes of cases which he had seen there, and from the results obtained from it in various patients whom he had sent to Carlsbad in previous years.

He had been in the habit of assuming for a long time past, from what he had noticed of the Carlsbad cure, that individuals suffering from troubles due to functional obstruction of the liver, and those with uncomfortable accumulations of adipose tissue, are most likely to be benefited by it; and his experience with regard to it had been exceedingly gratifying. In those affected with biliary calculus the action was very prompt and efficient, and as far as he had been able to judge, its use was attended with permanent benefit. Cases under his care, in which all the ordinary methods of treatment failed, have, after a course at Carlsbad, been entirely relieved. It was usually advisable, however, for such patients to spend two or three consecutive seasons there. In several such cases that he recalled there had been no return of the attacks after the lapse of four or five years. Dr. Otis described with considerable detail the case of a gentleman, sixty-five years of age, suffering from aggravated liver, the results of high living, whose condition, notwithstanding the fact that for two years he had been most abstemious in his habits, and in spite of all treatment, gradually grew worse and worse, until he was taken, in a very weak state, to Carlsbad, when he immediately began to improve. At the present time, at the age of sixty-nine or seventy, he was apparently one of the healthiest men in the city of New York; and so decided had been the effects of the Carlsbad treatment that, since taking it, he had been able to resume habits of life which are simply astonishing in a person of his age. The same results, he said, he had seen in repeated instances under his observation.

That which decided him to try the Carlsbad treatment himself was the existence of gout, and what he supposed to be gouty dyspepsia, which was attended with more or less mental hebetude and an inability to attend properly to his usual professional work. While at Carlsbad he daily took, at short intervals in the morning, five seven-ounce glasses of the water at a temperature not exceeding 80° F. The regimen to which he was subjected involved the avoidance of starchy food, but allowed a sufficient amount of nourishing diet; and he took two glasses of claret a day. Although using only a very moderate amount of exercise, he lost one pound a day for thirty days, and among the results produced by the treatment was a considerable loss of strength. He experienced more or less debility for a month after leaving Carlsbad, spent principally in Switzerland; but he gradually improved in flesh and strength, and at the present time he enjoyed an amount of freedom from dyspeptic trouble which he had not had for a number of years. His own experience was also that of a good many other individuals with whose cases he was well acquainted.

Aside from the diet, and the regular habits imposed upon those taking the treatment at Carlsbad, he believed that there was something in the water which tended to the elimination of effete material from the system. This was what was needed in the class of cases under consideration, and, in general, he had found that those remedies which produced this result were the most valuable. Thus, mercurials were of very great service, and patients with the uric-acid diathesis were immediately benefited by their regular administration. In such cases, from one to three grains of calomel a day could be taken for a considerable time with great advantage and without producing any deleterious results.

THE CHAIRMAN said that individuals who had too much fat, and those who had an excess of uric acid, would derive the greatest possible benefit from the course at Carlsbad; but for those suffering from Bright's disease, or pulmonary trouble, or from any grave depression of vitality, it was only attended with evil. He had, however, expressed his views on this subject very fully in a paper published in THE MEDICAL RECORD in October, 1886, and would not go into any details on the present occasion.

DR. WILLIAM H. THOMSON read a paper on

AUTO-INFECTION FROM GASTRO-INTESTINAL FERMENTATION.

He said that in the outset he would relate some cases in which auto-infection resulted in the production of serious nervous troubles, and then make these the text upon which to base some general remarks on this subject.

CASE I.—This was a lady, fifty years of age, the subject of Graves' disease. She had been suffering from diarrhœa all summer, and was affected with excessive nervousness. The enlargement of the thyroid and the exophthalmos were slight. There was no albuminura, and no casts in the urine. In spite of all treatment she continued to grow worse, until, finally, she was placed upon an exclusive diet of Arabic fermented milk. No medicine was taken, except some bismuth and pepsin powders. Under this treatment she rapidly improved, and at the end of two months she was practically well. She then returned to a mixed diet, but finding that the diarrhœa came back, resumed the fermented milk. After a time, however, this became so distasteful to her that she was unwilling to continue it any longer. Professor Thomson then treated her for a year, and at the end of that time he found the condition greatly aggravated, the exophthalmos and enlargement of the thyroid having increased very much. Fermented milk now had no effect, and after a time she died very suddenly. It would seem, he said, that in this instance the milk for a time arrested Graves' disease, and in other cases he had acted on the same basis.

CASE II.—This was a gentleman of leisure, thirty-five years of age, suffering from dyspepsia and hypochondriasis. His chief trouble was palpitation of the heart and a rapid pulse (the beats never being less than 120 to the minute), though there was no organic cardiac trouble. The patient was not at all dissipated in his habits. He was relieved by bismuth and powdered calumba. This was evidently a case of poisoning from gastro-intestinal fermentation.

CASE III.—A gentleman, fifty-four years of age, with gout for twelve years. After poisoning himself with an overdose of a patent medicine, known as Reynolds' specific, he had a watery diarrhœa, which had a definite relation to certain head symptoms. Whenever the diarrhœa was present he was troubled with mental cloudiness, and whenever constipation could be induced his mind was clear. During the past year very good results had been obtained from the use of salol, sodium, benzoate, and charcoal. The patient was unable to take salicylate of soda or naphthaline. Here, also, was unquestionably an instance of poi oning from intestinal fermentation.

CASE IV.—A gentleman, fifty-four years of age, the subject of peptic insomnia, whose father had suffered in the same way. He would sleep on first retiring, but always woke after three or four hours. For a time he had taken salicylate of soda with some benefit, but it had to be given up on account of its unpleasant effects, and during the last three months better results had been obtained in his case from creoline, with charcoal as an excipient.

CASE V.—This was an unpromising case of epilepsy in a lad seventeen years of age. He was first seen by Dr. Thomson, in October, 1886. The epileptic seizures had followed an attack of what was diagnosed as cerebro-spinal meningitis when he was three years old, and had continued ever since. The attacks were always preceded by pain in the stomach, and a comatose condition continued for a number of hours, and until the appearance on the body of a general eruption like urticaria. For some years his parents had given up all hope of relief, and when he came under Dr. Thomson's care the latter was requested not to give him any bromides, as they always made him worse. The seizures were often as frequent as two a day, and he found that they were always preceded by a watery diarrhœa. He also found that they were preceded by fetid breath. The principal agents employed in the treatment were turpentine resin, salicylate of soda, bismuth, and resorcin. The patient improved in general health, but not as regards the number of the epileptic attacks. He then employed picrate of ammonia and digitalis, with the result of preventing the attacks altogether. After a time, however, these remedies were discontinued, and in March, 1888, the patient had a fit. The attacks then recurred about once a week, though the breath was never offensive again. The picrate of ammonia and digitalis were now resumed, but this time they failed to have the desired effect. More recently the patient had been taking salol, nitrate of silver, and other remedies with benefit. This case can be regarded also as one in which there were plain indications of intestinal fermentation.

Dr. Thomson then went on to say that it could no longer be doubted that the intestinal canal might be the seat of the generation of violent poisons, the result of bacterial action, which were as active as any poisons that could be introduced from without. This was clearly shown in both typhoid fever and cholera, and Koch had demonstrated that the cholera bacillus runs through its entire course in the intestines. The poisons eliminated in the intestines acted like pancreatine, and, like it, had their effect increased by such substances as sodium carbonate. It was indisputable that many disturbances of the economy were primarily due to such poisons generated in the intestines, and this was especially true of functional derangements of the nervous system. This subject had been greatly elucidated during the last ten years by the investigations of Brieger, Selmi, and others, in regard to the ptomaïnes. While many of these were inert, there were others possessing every variety of deleterious influence, which closely resembled some of the vegetable alkaloids in their qualities.

Having referred more particularly to indol, he said that *à priori* we would expect that the intestinal canal, from the conditions known to exist there, would be likely to admit of such changes in its contents as would evolve products which would give rise to many distinct forms of nervous disturbance. He had long been convinced that there must be an essential difference between those forms of nervous disease which were intermittent in their character and those which were constant. If they were intermittent he did not believe that there could be any organic lesion, while, on the other hand, if the symptoms were constant the disease must be organic. These considerations, Dr. Thomson said, had a bearing upon the treatment. He agreed with Wilks that migraine and epilepsy were mutually exclusive. If an individual had one of these troubles, he would be free from the other, and the two affections were never interchangeable. He considered epilepsy a functional disorder from the fact that it was intermittent.

Since there was this constant tendency to fermentation, and the elimination of poisons in the intestinal tract, it might be asked, What is our safeguard from their dangers? The answer was, The character of the natural secretions. They were, in the first place, digestive, and secondly, powerfully antiseptic. In so-called uræmia, the condition was due rather to the excretion of intestinal alkaloids than to the excretion of urea, and from his belief in the liability to the generation of such poisonous products in various states of the system he had been led to employ antiseptic agents very largely in his practice. For a long time past he had been in the habit of treating migraine as dependent on defective innervation of the alimentary tract. In typhoid fever he used bismuth freely, on account of its antiseptic qualities. Among the other antiseptic agents that he had found most useful were resorcin, in five-grain doses, benzoate of soda with salol, and creoline with charcoal as an excipient. In looking back over the past few years in his own practice, he could observe, therefore, a marked change in the treatment which he adopted in various affections, the tendency being constantly toward the more general use of antiseptics.

DISCUSSION.

DR. H. N. HEINEMANN said that up to the present time our scientific knowledge was not sufficient to inform us, with the exception of indol and one or two other similar agents, precisely what the poisonous elements referred to in the paper were. They no doubt existed in three forms: (1) liquid alkaloids, (2) gases, and (3) bacteria. There could be no question that lithæmia or lithiasis, and many other conditions, were due to gastro-intestinal infection, and it would probably be found that the principal agents causing such infection were generated in the small intestine. As our knowledge of such conditions increased it would also, no doubt, be found that there were certain substances, each of which gave rise to a distinct variety of disturbance in the system. In this connection Dr. Heinemann referred to the entirely different symptoms produced in rabbits by tetanine and two other poisons derived from the animal economy which he had observed in Briger's laboratory during the past summer.

DR. W. W. VAN VALZAH referred to a case of epilepsy which he thought went to confirm Dr. Thomson's views in regard to this disease. It was observed that invariably after an attack (no matter how long the latter lasted) the patient vomited the food taken before the seizure. Although the trouble had been supposed by different physicians to be due to various organic conditions, it was a fact that under the use of a regulated diet and remedies addressed to the alimentary canal the patient had now gone for six months without having a single attack, when previously they occurred very frequently. He said he would like to know something more definite in regard to the method which Dr. Thomson employed in ascertaining the conditions present in his patients. He had found that, as a rule, physicians depended entirely too much on the accounts given by the patients themselves, and consequently neglected to make the thorough examination which was often essential to success in the treatment. Personally he made it a point to study each case with the greatest possible care. He noted the physical signs and the symptoms present, and examined not only the urine, but the microscopical condition of the blood and the gross and microscopic appearances of the stools. In this way he was able to get a definite knowledge of the digestive and assimilative powers of the patient, and he had found that this method afforded very satisfactory results.

DR. THOMSON said that in the limits of one paper it was entirely impossible to go over all the ground that would be involved in an exhaustive study of this extended subject. As to the examination of his patient, he had been accustomed to pay close attention to groups of symptoms,

and, beginning at the mouth, he questioned the patient very carefully in regard to the condition of the alimentary canal. The derangements connected with the stomach were quite different from those connected with the intestines. In migraine, the condition of the urine often varied very greatly at different parts of the day, and its characteristics at the beginning and at the end of an attack were different. It was sometimes possible to abort an attack, and for this purpose ergot was one of the most efficient agents that could be employed. Where there was gastro-intestinal fermentation the pulse was always of high tension.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, December 19, 1888.

R. C. M. PAGE, M.D., PRESIDENT, IN THE CHAIR.

DISCUSSION ON DR. JACOBUS' PAPER (see p. 117).

THE patient was exhibited for the purpose of showing the median and lateral scars; the foreign body found in the vermiform was also exhibited, supposed to be a bean; also an elastic abdominal bandage for use in similar cases.

By way of illustrating the complications of appendicitis, perforation, abnormalities of the vermiform, etc., DR. GRAUER exhibited the following specimens:

1. A vermiform appendix, nine inches in length, running up to the liver.

2. Perforation of the vermiform, with general peritonitis, in a lady upon whom an abortion had been performed. Death had been supposed due to the abortion, but the perforation had evidently been its cause.

3. Biliary calculus in a vermiform appendix, illustrating a possible element of occlusion.

4. Atresia of the vermiform appendix.

5. Tubercular ulceration of the lower part of the vermiform.

6. Ulceration of the body of the vermiform appendix.

THE PRESIDENT announced that during the past year there had been three successful cases of operation for perforation of the vermiform under treatment by members of this Society, viz.: Dr. Baruch's case, operated upon by Dr. Sands; Dr. Dessau's case, operated upon by Dr. Burchard; and Dr. Jacobus' case, operated upon by Dr. Wylie.

DR. WYLIE said for some time past he had been looking for just such a case and was very glad to have the opportunity of operation, feeling satisfied that some recent cases of prominence had been lost by incomplete methods of operating. It will not do in such cases to merely open the abdomen, let out the pus, and put in a drainage-tube or iodoform gauze. Where there is general peritonitis a free opening should be made and all adhesions broken up, so as to prevent intestinal obstruction, and to be certain to get at all collections of pus and wash them out.

Suppurating peritonitis is characterized by the formation of pockets or puddles of pus between the adherent coils of the intestines, which must be loosened up to be washed out. In this case, even after washing out with two gallons of hot water, the hand was again passed into the abdomen and pockets of pus found that had not been touched by the first washing, and this was repeated three times before assurance was had that all of the pus had been cleared out and the intestines loosened so as to lessen the chance of intestinal obstruction, which is about as dangerous as the sepsis in such cases.

Recently the general surgeons have gotten into discussions about intra- and extraperitoneal abscess. With gynecologists it was an old question, and by the younger members considered settled in favor of intraperitoneal abscess several years ago. Abscesses about the appendix are very much like abscesses about the Fallopian tubes, and the pathology is very much the same. Acute phlegmons, or acute lymphangitis, or phlebitis, does exist in the cellular tissue; but it is known now, beyond any reasonable doubt, that pelvic abscesses are, with rare exceptions, always intraperitoneal. These abscesses are often found pushed below the normal level of the peritoneum, but this is due to the effort of nature to expel the dangerous substance out of the peritoneum.

When the symptoms indicate the formation of pus within the abdomen or pelvis, if it cannot be detected and readily opened with safety at a point where the sac is adherent to the floor of the pelvis or abdominal wall, without opening into the general cavity of the peritoneum, then an exploratory incision should be made, first to find the pus; when found, if the sepsis is marked, then, if possible, the opening to evacuate the pus should be made by the vagina, or at a point where the wall of the pus cavity and the parietal peritoneum are adherent. If this cannot be safely done, then, instead of adopting Mr. Tait's suggestion of opening the pus sac, washing it out, and sewing the sac into the opening in the abdomen, Dr. Wylie empties the sac of pus with a trochar, then carefully washes out the pus cavity with a 1 to 2,000 solution of bichloride, and having thus rendered it aseptic he proceeds to enucleate the whole pus sac, with the diseased tube or ovary, and thus do a complete, instead of an incomplete, operation. After removing the pyogenic sac, the abdominal cavity should be washed out with great care and a drainage-tube put in. In a large experience with abscesses about the pelvis, he has, with a single exception, always removed by enucleation all abscesses by the above method. Several times he has tied off the appendix when involved in the wall of abscesses about the right tube and ovary, but his experience with perityphlitis has been limited to three cases. The first case was seen in a medical ward of Bellevue Hospital. There was high temperature, sweating, and local tenderness, but with these symptoms two of his colleagues could not make out the presence of pus, and advised ice-bags, etc. Another colleague agreed as to the advisability of opening the abdomen, which was done, and more than a pint of very fetid pus was emptied out. The patient made a complete recovery in three weeks.

The second case occurred to the husband of a woman from whom the tubes and ovaries and a large pelvic abscess had been removed. Dr. L. A. Stimson saw the case in consultation. The history was the usual one of irregular temperature, localized pain, etc., but the man was so fat that only the faintest signs of pus could be made out. When he took ether his temperature was absolutely normal, and pulse 72, and his bowels had moved without difficulty, but there was found a full pint of very offensive pus, which was evacuated and a drainage-tube put in, and he made a good recovery. The pus was so completely shut off, that, at the time, the general system was not affected, but without the operation he would have had very little chance of getting well.

The third case is the one just reported by Dr. Jacobus. The two points of highest importance are: 1. If it be a case of general peritonitis, due to the bursting of an abscess, the abdomen should be opened freely, and all intestinal adhesions should be broken and all of the pus washed out and drainage established. It will not do in such cases to merely open the belly, wash out the original abscess, and put in a drainage-tube, although the latter treatment will do if the peritonitis is localized, even though the abscess is large and the symptoms simulate general peritonitis.

2. That even in local peritonitis it is better surgery to wash out the sac of the abscess and enucleate the sac than to sew it to the abdominal wall.

DR. ROBERT ABBE considered the main points in controversy—the use of physic before operation and the use of the abdominal douche. Some time ago it had been generally conceded that physic before operation for perityphlitis was wrong. The speaker still adhered to this view. The mechanical conditions were not such as to require physic. There was very rarely a loaded cæcum

in these cases. The trouble was in the vermiform. The voluminous secretion produced by physic, and the increased peristalsis was apt, he thought, to favor the escape of fecal matter into the peritoneal cavity, or to precipitate rupture, where this had not already occurred. After operation there was no question as to the value of laxatives. Where the temperature rose there was nothing which acted so well as a saline administered after Tait's suggestion; before operation he thought the enema a better and safer method of clearing the lower bowel.

The speaker regretted that Dr. Weir was not present to defend the statement credited to him by the author of the paper. During the past summer he had himself had a case of perityphlitis, which had ended disastrously. The patient had been up in Vermont when seized with the attack, and had sent for him to the east end of Long Island. A subsequent telegram that the patient was better, and again another stating that he was worse, resulted in a delay of forty-eight hours. He mentioned the fact of the transient improvement because it was so common in these cases. There was some further delay in securing suitable assistance, and the operation was done upon the fifth or sixth day, when the patient was suffering from shock and other evidences of perforation. The median incision was used. An accumulation was found upon each side of the median line. A half-pint of pus was liberated, with four fecal concretions. Adhesions extended transversely across the abdomen, so as to divide the cavity into an upper and a lower portion. The upper part was not invaded. With the concurrence of Dr. Weir, however, he had thoroughly explored and washed out the whole cavity. The patient had rallied after the operation, but at the end of the third hour had commenced to decline in strength, and at the end of six hours had died. Dr. Weir had subsequently agreed with him in thinking that both segments of the abscess might have drained through the central incision, and in belief that the shock of the irrigation had been a factor in the fatal issue. They had agreed that it was better to limit irrigation to the abscess-cavity. The speaker had had twelve or fifteen cases in all, and in every instance he thought that the intestines had been coated with lymph. It was the usual condition, yet these patients had recovered. Recovery was, indeed, the rule after operation in these cases.

The question of different varieties of infection should be taken into consideration. Other organs—the tonsils, for instance—might be subjected to both a low and a high grade of infection. He saw no reason why the same fact might not be advanced here. There were some cases which were apparently fatal from the outset. He thought, however, that the percentage of deaths would be found higher where general irrigation was practised, than where simple drainage was relied upon.

Dr. W. T. Bull expressed his pleasure for the privilege of examining this patient and hearing the interesting report. In its diagnosis and treatment the case was a brilliant one, and he could not add anything to the good and precise summing up made by the author of the paper. He failed, however, to recognize the case as a perityphlitis. The treatment of general peritonitis by laparotomy, breaking adhesions, and washing out was conceded. Had the case been taken in hand earlier, however, these measures would probably not have been required. Upon the third or fourth day there had probably been a circumscribed peritonitis. Operation then would have prevented general peritonitis. He had no desire to belittle the operation as done, but simply wanted to call attention to the value of early diagnosis and prompt treatment in these cases. It was better to avoid a general peritonitis than to cure it after it had developed.

The speaker referred to the fact that Dr. Parker had been the originator of the practice of opening these abscesses. The previous opening of the peritoneum did not practically alter Dr. Parker's operation.

The question of intra- or extraperitoneal origin was, he thought, settled. All were primarily intraperitoneal. The cases of operation and autopsies in which the cæcum was found outside of the peritoneum, and the cases in which the abscess was found behind the peritoneum, would show a previous attack of perityphlitis as the agent which had shut off the cæcum and made it an extraperitoneal organ. Although, however, the abscess was intraperitoneal, not a very thorough laparotomy was required to reach the collection. The tendency of peritonitis was, as had been said, to shut off and encapsulate its products. Dr. Parker's rule had been to incise down to, but not to open, the peritoneum. If pus were found, evacuate it, if not, close the wound. Parker's operation had required modification only. We now incised not only the abdominal wall, but the peritoneum and whatever else intervened until pus was reached. The end of the first week he thought the most critical period in this disease.

The speaker had found the needle very useful in localized inflammations where the presence of pus was uncertain. He had never seen any harm from its employment. In one hospital in this city it was at one time the custom among the house-staff to plunge the needle perpendicularly into the abdomen of every patient in whom there was the smallest suggestive symptom, and no harm was known to have followed. He did not endorse such an indiscriminate use of the needle, and did not approve of its perpendicular insertion. When using the needle in this disease he inserted it obliquely, plunging it first near the iliac border and then into the lumbar region, pointing it forward and inward to the location of the cæcum. Pus was apt to burrow in this location. By the use of the needle time was gained and burrowing avoided. In operating for perityphlitis it was not desirable to wait for the signs of general peritonitis—vomiting, tympanites, and distended abdomen. One should operate when there were any signs of local peritonitis, and if in doubt use the aspirating needle to settle the diagnosis. The speaker would not, however, encourage unnecessary operations. Three cases had been recently reported from Boston in which apparently resolution would have occurred spontaneously if undisturbed, but this was not the usual history. Usually operation was undertaken too late. On the other hand, the exploratory incision in the iliac region was no more than a simple stab-wound, where the intestines were not punctured. All knew that this was not a dangerous injury, several thousand so injured having recovered during the late war.

Dr. R. G. Wiener had operated upon six cases in two years. One of these cases had illustrated Dr. Bull's statement in regarded to the value of early operation. He had operated within forty-eight hours after the appearance of the local symptoms upon a slight increase in the temperature and pulse. He had made the lateral incision, and had come down upon the appendix in a gangrenous condition. There was no suppuration and no peritonitis, and after the first twenty-four hours the man's temperature had been normal. Another case was that of a man upon whom he had operated at the end of seventy-two hours, and death had followed within twelve hours. One could not tell whether a case would eventuate in an encapsuled abscess or general peritonitis. When in doubt laparotomy for exploration was clearly indicated. The incision should do no harm.

Dr. Jacobus inquired whether Dr. Wiener gave laxatives or opiates in the after-treatment of his cases.

Dr. Wiener had not given laxatives, and but little opium. The bowels had moved spontaneously, as a rule.

Dr. Baruch asked whether Dr. Wiener had noted any special decubitus in this disease.

Dr. Wiener replied that the abdomen had been rigid, but no special decubitus had been noted.

Dr. Leale had been accustomed to follow Dr. Parker's directions in circumscribed abscess. He regretted that the author had not mentioned Dr. Parker in his paper, as he had been one of the pioneers in the treat-

ment of this disease. The recommendation of elaterium as a cathartic, also, he would criticise on account of the vomiting produced by it. He had used the best Clutterbuck's elaterium, and while it was invaluable where large watery accumulations were to be carried off, the vomiting would contra-indicate its use after laparotomy, where tension upon the sutures was to be avoided.

Dr. J. Lewis Smith raised the question of preliminary treatment. The patient was first seen by the general practitioner. Formerly poultices had been used during the initial stages, but of later years the ice-bag had been more generally employed. He asked which the surgeons present preferred as a preliminary application.

Dr. Bull did not think that either application made any difference in the ultimate result. The cutaneous œdema produced by a poultice somewhat obscured the local evidences and made the diagnosis more difficult; but, on the other hand, the poultice was more grateful to the patient, as a rule, and there was no essential reason why it should not be employed.

Dr. Baruch felt that the life of the patient was, after all, in the hands of the general practitioner, as he would see the patient first. The question of diagnosis was of the greatest importance. If the diagnosis could be made out, the treatment was clear. He had lost four cases by perforation when he had had medical counsel. With surgical counsel he thought that they might have been saved. Last winter he had called in Dr. Sands, and the case had recovered. As aids to diagnosis he had depended upon the tenderness in the right iliac fossa and the peculiar decubitus. The right leg was drawn up.

Dr. Dessau referred to a case where he had called in Dr. Smith and Dr. Wyeth, and an ice-bag had been recommended. Resolution followed. In another case, with eminent counsel, poultices had been used, and resolution had followed. It seemed immaterial which were used. On the score of comfort he thought the ice-bag was to be preferred. It was more easily applied, was steadier in its action, and was better borne. He had used the aspirator for the purpose of diagnosis and never had seen any bad result.

Dr. C. S. Wood remarked that the death of the patient should not always be ascribed to delay on the part of the general practitioner. He related the case of a boy, found on the third day in a tenement-house, in a hall bedroom. Peritonitis was recognized, he was removed to the New York Hospital and was operated upon that same night, but before the noon of the next day he was dead. The blame could not be attached to the general practitioner in this case.

Dr. Wylie spoke in regard to the use of the aspirating needle for diagnosis. The danger lay in cases where pus was found. It was to be remembered that the sac of the abscess was rounded, and that while one of its aspects was adherent another might be free. If the abscess were punctured through its adherent portion no harm would result. If punctured through its free portion, however, even the prick of the hypodermic needle might give exit to its contents into the peritoneal cavity. This had happened in Bellevue, the abscess had evacuated itself, and within twelve hours the patient had died from suppurating peritonitis. In cases of doubt, where there were chilly sensations or an elevation of temperature, it was safer to open the abdomen in the median line and explore. He had been the first, at least in this country, to adopt Tait's practice in regard to saline laxatives. From close observation of a number of cases, however, he had come to the conclusion that this catharsis acted by relieving obstruction either in the bowels or vital organs, and not by the removal of poison alone. He repeated his opinion that the essential lesson to be gathered from the case of the evening was the safety and the value of thoroughly breaking up the adhesions in these cases.

Dr. J. D. Bryant, unable to be present, sent the following note: "December 19th, 9.30 P.M. I am much obliged for the opportunity of advocating, as I should have done, early operative procedure and avoiding loss of time in making refined diagnoses."

Dr. Jacobus closed the discussion. He had referred to Dr. Weir's paper simply to call attention to the extraordinary heat of the water used in the irrigation. If so warm that the hand could not be borne immersed in it, he thought that it might easily have caused shock. If the death of the patient could be traced to the irrigation this excessive heat was probably its cause. To Dr. Abbe's objection to the laxative before operation he would only say that in this case the laxative had apparently acted beneficially. If the patient had not got up he thought that resolution would have followed upon the improvement of the second day. This improvement might have been attributed to the antipyrine, however, known to be one of our most excellent antiphlogistics. He repeated his statement that any evidences of peritonitis were sufficient to justify the exploratory operation. A fine diagnosis was not required.

Stated Meeting, January, 16, 1889.

A. M. Jacobus, M.D., President, in the Chair.

DISCUSSION ON DR. FRUITNIGHT'S PAPER (see p. 122).

Dr. Blumenthal had been surprised to learn that the tendency to vesical and renal concretions was so great among children. In his practice, extending over a good many years, he had seen some cases of obstruction and retention, but these had been relieved without dilatation or operation, the force of the stream of water driving the stone through. He had been glad to hear the author emphasize the dietetic management of these cases. The statement of cure by operation was doubtful if the tendency remained. After-treatment to combat the diathesis was equally required.

Dr. Wood also had been surprised to learn of the relative frequency of this difficulty in children. He had been especially interested in the European prevalence of the condition. He thought that there was no such number of cases here. Poor assimilation was the original cause. Scrofula and all the predisposing causes were more common in the older countries where the poverty was great. In his practice he had not found anything like the same proportion of cases. The dietetic management was all-important. He referred to a case of urethral calculus upon which he had successfully operated. Concretions under the prepuce were due to smegma in all instances, which might give rise to some irritation, but not in an extreme degree. Where the child was always pulling upon the penis and working with it he had, as a rule, found phimosis, and operation had been required to relieve the difficulty. He referred to the case of a girl, of eleven years, where he had dilated and removed the stone. This child was, as noted by the author of the paper, of strumous habit and surrounded by bad hygienic influences.

Dr. Caillé, on invitation, spoke, referring to a case in a girl whom he had found in bed, complaining bitterly of pain, and evidently suffering from intestinal or renal colic. The next day the pains had been relieved, but the parents stated that the child passed no urine. Examination showed the presence of urine in the bladder, and on using the catheter a slow stream was obtained followed by a gush and the expulsion of a small stone.

Another case was that of an infant, a few days old, who refused the breast, moaned, and drew up its legs as in colic. The napkin showed spots with a reddish centre. Palpation disclosed tenderness of the lumbar region. Under treatment with warm baths the distress was relieved, but the child died three days later. The autopsy showed acute nephritis. The diagnosis of renal colic was easy in some cases but in others very obscure.

Dr. Milbank thought the paper of the evening most valuable. The literature of the subject was not abundant, and statistics not full. He had seen a few cases of stone in the bladder in children, and many cases of the uric acid infarctions in the new-born. Since learning of

the subject of the evening's discussion he had examined about forty bodies in his service at the New York Infant Asylum. Among these had been a number of cases of kidney infarctions, but no cases of stone. The cases had been in children from two months to three years of age.

DR. PECK considered the symptomatology of the paper particularly valuable as directing attention to the fact that not every colic, not all the screams of young children were due to intestinal trouble. An interesting thesis was propounded by Sir Henry Thompson, ten years ago, at his clinic in the University College Hospital, London, viz.: "Why do we find vesical calculus among the adult rich and the infantile poor, and not *vice versa?*"—a thesis which still remains unanswered. Uræmia and urinary concretions were interesting to the ophthalmologist not only for the changes in the retina and the optic disc, but also for symptoms connected with the pupils and the ocular muscles.

DR. PAGE referred to two cases for which he had called upon Dr. Markoe in consultation. The symptoms were those of stone, but circumcision gave complete relief. The same relief might possibly have been given by washing the glands with warm water and borax. He regretted not having at least tested this treatment.

DR. DESSAU had seen a large number of children, in dispensary and private practice, and could recall but a single case of stone. This was in a boy, six or seven years of age, who presented a small calculus, one inch behind the meatus, discovered by palpation and the probe. Manipulation brought the stone to the meatus, when the forceps removed it. Stones were most likely to lodge in the fossa navicularis, the smallest portion of the canal. Diet, cod-liver oil, and hygienic surroundings were of the utmost value in the treatment of the condition.

DR. BLUMENTHAL desired to emphasize the value of physical exercise in the open air.

DR. PECK asked whether Dr. Fruitnight had in the course of his recent reading found that rheumatism and rheumatic gout went hand in hand with lithiasis in children.

DR. FRUITNIGHT had not found this association noted.

DR. DESSAU inquired whether the calculus spoken of as urethral had been supposedly formed in the urethra or simply washed down.

DR. FRUITNIGHT replied that it was generally washed down. In only one case had it been demonstrably formed in this location. In closing the discussion the speaker emphasized the hygienic measures to be used in the treatment of the condition.

BACTERIA IN THE GLACIERS.—Dr. Schmelk, of Christiania, has found vast colonies of bacteria in the ice of the Jerstedalsbræ glacier and in the streams fed by it. They appear under the form of rods, and resemble the bacillus fluorescens liquefaciens. During their period of growth these bacteria emit a fluorescent material. They multiply with great rapidity during periods of thaw.—*Centralblatt für Bacteriologie.*

AN EASY WAY TO GET PREVENTIVE VACCINES.—Professor Bouchard, writes a correspondent of the *Berlin Medical and Surgical Journal*, lately communicated to the Academy of Sciences a note to the effect that the soluble matters manufactured by microbes may pass through the body of the animal in which they exist, and be eliminated by the urine, preserving at the same time their property of conferring immunity, as shown by the researches of MM. Charrin and Ruffer. To test the value of these researches, Professor Bouchard inoculated healthy animals with the urine of an animal affected with a virulent malady, and the result was that the healthy animals appeared to have acquired immunity just as if they might have been vaccinated. The urine may therefore be said to have behaved as a veritable bouillon of culture.

Correspondence.

IS THE PRACTICE OF MEDICINE A FAILURE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If it be true that THE MEDICAL RECORD is a round higher on the ladder than any other American medical journal, the offence is due in part, no doubt, to the editor, whose effusions always furnish instruction, amusement, or food for thought, and sometimes all three. That the editor feels the importance of his position is indicated by the fact that from his elevated perch he sees far enough from his base to begin to be honest with himself, the world, "and the rest of mankind."

Being something of a visionary and dreamer, the writer has been accustomed to direct his mind's eye into the unexplored mists of the future for a sign of the coming millennium, when all professional (medical) men could be honest with themselves and their patients, and still find bread to eat. If he could in any way contribute to the hastening of that event he might indeed thank God that his servant had beheld his glory, and betake him to "the drapery of his couch," and "lie down to pleasant dreams." But to the question, When can such things be? "we offer no positive answer."

In considering the question, "Is the Practice of Medicine a Failure," THE MEDICAL RECORD very properly, I think, eliminates from the inquiry surgery and hygiene.

Surgery has become a great art, so great that even the abuses which beset it in special directions are no offset to its grand and beneficent results. True, the man who suggested aspiration of the heart was not confronted by a writ *de lunatico inquirendo*, nor has Alexander's operation ceased to be done; but the evils of rashness will correct themselves, and the men who now spay for fame will surrender the field to men who spay to save life.

But what if Nemesis should overtake the rash aspirants for fame! Woman is being "unsexed" in various ways. She is crowding man in every "liberal" calling—more in medicine, perhaps, than in any other. Suppose she should get on top before the advent of the medical millennium for which the writer has been praying. We may then find our cremasters tucked and fluted for pendant scrotum; the prepuce flounced for redundancy; the epididymis resected when the testicle is too low; our ureters catheterized, and the pelves of our kidneys curetted; and Miss Cynthia Tate, more bold and brilliant than all the rest, will castrate for all manner of neuroses. Then the sins of the fathers shall be visited upon the children for generations, perhaps.

Hygiene, however, is the direction in which the finger-board of future glory seems to me to point. Few people, relatively, require the art of the surgeon. All are intensely interested in the causes which develop disease, and the means of removing the causes or preventing the development. Of course there are certain causes inherent in the race which science cannot remove. It can only point the way, and trust to the slow process of evolution to make man master of his appetites, everyone of which, indulged to excess, becomes a source of disease. But man's environment is more easily controlled, and there is reasonable hope that the plagues and epidemics which have decimated communities in the past will be substantially, if not literally, banished. A wide-spread epidemic of yellow fever, with a percentage of death below the rate of most acute febrile diseases, is certainly remarkable, and, in spite of Sternberg and soda, it is too early to give the credit to therapeutics; for did not the negroes say that the colored people who sent for the doctors died, while those who threw "physic to the dogs" got well?

We will accept it as definitely settled, then, that the practice of medicine, so far as surgery and hygiene are concerned, is not a failure. This leaves two branches of the inquiry open to discussion: 1. Is the practice of medi-

cine a failure from a purely business stand-point? 2. Is it a failure from a therapeutic stand-point?

The writer's observation extends over portions of a majority of the States of the Union, a minority of the Territories, and the District of Columbia. I estimate, first, the number who enter the profession; second, the number who succeed; third, the number who do fairly well; fourth, the number who exist; and, fifth, the number who fall by the way. Comparing them by this scale with the numbers who enter commerce, the law, and the ministry, I am persuaded that the practice of medicine, from a business stand-point, is not a failure. The percentage of successes seems to me to be quite as large in medicine as in the other callings.

The classes who enter these pursuits in the country generally average much the same, and succeed or fail for much the same reasons in each.

And herein arises the point of real interest which attaches to the study of this question. The most cruel falsehood ever engrafted upon science by the phrase-makers is the modern dogma of "the survival of the fittest." The fittest never did, and I fear never will, survive by virtue of fitness. The *strongest* survive, not the fittest.

It is the "good" who die young, the pearls that are trampled under the feet of swine, and "modest merit" that is crushed to earth by arrogant assumption!

Men succeed or fail, in any calling, in consequence of a *personality* which bears no relation to knowledge or skill. No doctor ever succeeds solely by reason of knowledge and skill, nor fails solely for lack of knowledge and skill. Knowledge and skill are good, but of themselves they never bring business success. Some of the highest examples of knowledge and skill in the profession that I have met were conspicuous failures from a business stand-point; while some of the most brilliantly ignorant examples were among the most brilliant business successes, being the most idolized by the laity, in consequence of certain personal and social characteristics. When the lay mind finds its man, it finds its doctor.

I am aware that it is not easy for the successful doctor to grasp this truth. "We are all poor critters," and the wisest are too prone to lay the flattering unction of success to superior knowledge and skill, instead of giving credit to things which belong to the man and not the doctor—things which were as much a part of the man before he looked at a medical book as after he graduated.

Those of us who have enjoyed opportunities for extended observation have seen this truth illustrated in other pursuits; have seen the most profoundly read lawyer in his county—modest, retiring, sensitive—starve in neglect and seclusion until, through pity, his more successful brethren would secure his appointment or election as justice of the peace, where, as Squire Blackstone, he would manage to exist in dignified poverty, while Jack Goodfellow, a mere tyro in law and too restless to study, would grow rich in the practice of the profession. The profoundest students are not men of action.

Whether the measure of the doctor's success is sufficient to compensate for his loss in longevity will depend, I suppose, upon how you look at it. Money is not his only reward. In all other respects he is apt to pass at a very full valuation, and if he is hard-up, as he often is, his creditors are apt to be more considerate than with mankind in general.

Then considering, as I do, that the profession, though terribly crowded, is not more so than legal and mercantile ranks; and that its success on the whole is equal to the others, I must assume that, from a strictly business stand-point, the practice of medicine is not a failure—though, God knows, the pathway is sufficiently strewn with failures.

Is the practice of medicine a failure from a therapeutic stand-point?

Difficulties almost appalling stand in the way of a satisfactory answer to this question. Like the young man who inherited his father's estate, but who met such difficulties in the management of it that he "almost wished, sometimes, that father hadn't died," I almost wish, after having travelled so far, that I had not started to answer THE RECORD'S conundrum. But it has been my rule of action never to shrink from any task, no matter how difficult, if the patient's life was in danger and I could not shift the responsibility upon someone else, and I shall not shrink from this, as there is no substitute at hand.

Banish hygiene from the modern management of disease, and how far have we advanced from Hippocrates? Take measles, whooping-cough, scarlatina, any of the specific or continued fevers, and place them under the hygienic conditions that confronted Hippocrates, and can we cure any more than he cured?

Boerhaave was credited with the possession of all medical wisdom of his time, and the great volume through which he consented, after much importunity, to transmit it to the ages, was found upon his death to contain only this:

"Keep the head cool, the feet warm, and the bowels open."

Can we do more than Boerhaave enjoined? Can we do as much? Perhaps. We can open the bowels, we can aid in restoring warmth to the feet or in keeping them warm. We may be of service in keeping the head cool. But we may fail in all these.

Under like hygienic conditions, what can we do more than our fathers did to save life? Do we in all things do as well? What of the treatment of pneumonia, to which you allude with a humiliating array of figures?

Just here the image of a grand old man rises before me. He began to practise medicine about 1832. Thirty years later he stood before me as professor of practice in my medical Alma Mater. He was always happy when he came to pneumonia. He would say:

"Now, gentlemen, we will consider the most manageable malady in the whole catalogue of inflammatory diseases. I can take hold of pneumonia with absolute knowledge of the power of the means at my command."

Then he would describe with exactness the stage of the disease at which he bled, copiously or otherwise according to the strength of the patient, and the effect of that remedy; the stage at which he used antimony, and the effect produced thereby. Then, as if conscious that the tide against phlebotomy was setting in so strongly that not one student within hearing would dare follow his advice, he would raise his arms and voice excitedly and declare:

"Gentlemen, I am no Sangrado! I do not run around with a lancet always between my thumb and finger! I only tell you what my experience has demonstrated more than a thousand times."

I think the old gentleman's suspicions were well founded. I doubt if any member of his class ever practised phlebotomy. I never did. But, stranger than that, I have never lost a case of pneumonia, though I have treated some most unpromising cases.

"Treated," did I say? No, I never treat pneumonia. I just try to manage it, giving a little bromide to keep up appearances, a little Dover's powder if the pain require it, and whiskey in the form of eggnog and milk-punch later on. But as my experience with the disease is limited to a little less than twenty years in Dakota and Montana, where one lung is as good as two in the Eastern States, I claim no credit for treatment, and but little for management.

But would it not be well for some "bold, bad man" to study Marshall Hall, Dickson, Wood, and others—editions of forty years ago or so, and test their treatment of pneumonia as applied to modern conditions? There would at least be something novel in Marshall Hall's universal initiative in febrile diseases: "Bleed to faintness."

When I have seen an oily and unctuous brother, armed with Humphrey's specifics, create more enthusiasm than the best equipped regulars from the best schools, such faith as I had in men and drugs has suffered a great

shock. When I have seen the same brother, in order to evade prosecution for practising without legal authority, leave the town to the mercy of disease for five whole weeks, and return with a certificate from one of the leading colleges in the Northwest, and immediately add to his *clientèle* a larger percentage of merchants, bankers, ministers, and other intelligent classes than the most popular of the regulars, I have been on the verge of doubt. True, some of the lonesome regulars said he furnished more than his share of business for the undertaker. But then he had a right to. He had more material to work upon.

When I have seen a graduate of a noted university give the one four-hundredth of a drop of tinct. belladonnæ, I have at least wondered; and when I have utterly failed to establish a difference in mortality under the different systems of medicine practised under my own eyes, well —further remark is useless.

It has taken me twenty-five years to be convinced that so simple a thing as gonorrhœa cannot be cured, and I still cling to the belief that it gets well the quicker for a little judicious management.

But, my dear RECORD, we can do a great deal with drugs besides kill people What of the intermittents and syphilis? We can open the bowels, and sometimes close them; and how much better Nature often works after we have removed a part of her burden. We can relieve pain, often with more apparent good than harm. And when Nature's fight against the last enemy becomes hopeless, we can render her fall less shocking to the audience.

No, the practice of medicine from a therapeutic standpoint, though not a brilliant success, is not a failure.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 26, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	15	5
Scarlet fever	325	50
Cerebro-spinal meningitis	3	3
Measles	291	22
Diphtheria	176	39
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

A REMINISCENCE OF DR. C. R. AGNEW.—Charles Albert Sewall, Acting Assistant Surgeon, United States Army, of Whipple Barracks, Ariz T., writes: "When the doctor was on one of his tours of inspection, examining into the condition of the Indians at their various agencies in the Western Territories, in making a journey from the Mescalero Apache Agency, he stopped at the military post where I was in medical charge—Fort Selden, New Mexico, on the Rio Grande. It was a delightful experience to meet him socially, even 'way out on the frontier,' such a charming raconteur, so urbane and pleasant in every way as he was. In coming from the Indian agencies to the railroad he would often make long day trips in a stage or ambulance, and sleep at night in ranches along the way. 'Do you know, Doctor,' he said upon one occasion, when the subject of carrying a pistol came up, 'I have here in my pocket a most deadly weapon.' Knowing how peaceable ordinarily Dr. Agnew was, I was quite surprised, and continuing furthermore, he said: 'I have taken many lives with it.' 'How is that, Doctor?' I asked; and without any more ado he proceeded to take out of his pocket an insect powder blow-gun loaded for use, with the remark that he 'kept that for use on the *Cimex lectularius* which he had found to grow luxuriantly in the beds of our progressive citizens who emigrate to the Far West, and this was the only kind of a gun he ever carried.' I took him over my little hospital, and the following remarks were made by him, which I think are decidedly interesting. 'This hospital is very clean and neat,' said he, 'but I notice you have only plain beds with white spreads and bare floors in the wards. It has been our aim in New York to make our hospitals cheerful, as well as comfortable. A bright rug near the bed would help out, flowers growing about, bright colors in pictures and wall colorings, and to cultivate an air of cheerfulness as well as purity. Particular attention has been paid to the avoidance of hospital odor. Good cooking has been a desideratum, and the days of a hospital diet of "wedges of bread," "tannin tea," and "chunks of meat," are over, as far as our hospitals are concerned.' He was quite shocked at the way in which the Mohave Apaches treat their medicine men, referring to the custom of the killing of the medicine man by the tribe after the fifth death occurred among his patients. 'Poor untutored martyrs to superstition,' he called them. It is indeed a crying shame that these Indians do this thing every day in this enlightened age. I have seen a poor hunted Indian flee for his life to a military post, wounded and suffering, knowing that as soon as he left the protection of the military authorities he was doomed to instant death. I would here incidentally remark that this tribe is rapidly dying off with phthisis pulmonalis, and the barbarous misuse they subject all patients to, by treating them with a system of massage in which they frequently tramp the life out of the patient. I know of no more worthy field for philanthropy than the Mohave Apaches, for a more barbarous, superstitious, destitute set of human beings I never saw. If they acquire a competency in horses and food and clothes, such as it is, as soon as one of their number dies they cremate not only his body, but all his clothing, horses, food, and much of the same kind of material belonging to his friends in the tribe. They religiously believe that the thicker the smoke of the funeral fire, the more quickly his spirit ascends to the happy hunting-grounds. In this way the more funerals they have the poorer they are, and this custom bids fair to soon annihilate the tribe, keeping them constantly in an impoverished condition. The calmness and confidence with which one of these Indians looks upon approaching death, having, as he has, a firm faith in future happiness beyond the grave, would be a lesson to a Christian believer."

IS THE TASTE IN THE MOUTH?—Is it not a little singular that physicians will persist in speaking of the taste in the mouth? A patient was asked the other day if she had a bitter taste in her mouth in the morning. She naively replied that when she had a bitter taste it was always in her mouth. That is the only end of the alimentary tract that we know of in which the sense of taste resides.—*Medical Age.*

If our contemporary will be so particular, we may perhaps venture to remind him that, if one comes down to a minute analysis, the taste is not in the mouth in reality at all, but is in the gray matter of the uncinate gyrus. The idea that the taste is in the mouth is simply due to the eccentric projection of the secretion according to the known laws of physio-psychology. We trust that he will make proper explanations to the lady.

A NEW ASEPTIC AURAL SPECULUM.—Mr. A. J. Malony, the otacoustician, of Washington, D. C., has introduced to the profession a new aural speculum made of firm material resembling card-board, which, from its cleanliness and cheapness, offers some advantages over the metallic speculum. They are made after the patterns of Wilde and Gruber, and are so cheap that they may be thrown away after being once used.

INAUGURAL ADDRESS ON THE PRESENT NEEDS OF SCIENTIFIC MEDICINE.[1]

By ALFRED L. LOOMIS, M.D., LL.D.,

NEW YORK.

FELLOWS OF THE ACADEMY: The words to which we have just listened have quickened in me the consciousness that in accepting the honor you have conferred upon me I am entering upon grave responsibilities that demand an intelligence, judgment, and energy which cause me to distrust the wisdom of your choice.

As I review the good work that has been done in the Academy during the past four years, under the guiding hand of Dr. Jacobi, I am impressed with the fact that he has inspired all its departments of scientific work with his own indomitable energy and broad culture. He has laid the foundations of a far more comprehensive structure than existed before. He has striven to make this Academy the centre of scientific medicine in this city—I might say in this country. His labors have been unremitting, disinterested, and self-sacrificing, and he leaves the presidential chair with the highest esteem and gratitude of all its Fellows. How successfully the work which he has so ably begun was continued must be told by those who, years hence, shall write our history. It is our hope and purpose that the "well done," with which history has already sealed the record of the past, may not be denied to the future.

I desire this evening to speak to you of the "The Present Needs of Scientific Medicine in this City," and through you to the noble and broad-minded men and women, whose hands and hearts are in every enterprise that tends to make our city the centre of material power, art, science, literature, and human charity.

It were perhaps more fitting on such an occasion as this to indulge in mutual congratulations rather than in criticisms, to recall battles won, storms that are past, and to speak of the brightening skies that overarch our present successes; but to those who battle for science the time for congratulations come only when there are no new problems to be solved, no more wrongs to be righted, no faults that may be corrected, no needs that may be supplied, no new fields that may be explored, where faithful workers may perform greater achievements than have been reached in the past. Surely no one who reads with intelligent insight the lessons of the past quarter of a century, and who realizes the necessities of scientific workers in every department of human knowledge, can fail to be impressed with the conviction that a higher and broader culture is needed in those who are entering these fields of labor, and in no one is this more apparent than in that of medicine? That there have been great advances in this respect during the past twenty years few will question, but that the standard is still far below what it should be is equally apparent.

The remedy for this is somewhat difficult to reach; certainly the entrance examinations to our colleges which have been proposed do not solve the problem. It seems almost ridiculous that a few questions in mathematics, the elements of physics, and the rudiments of language, less difficult and less comprehensive even than those required for entrance into our academic colleges, can be a satisfactory criterion of a candidate's fitness to commence the study of medicine. It is to be remembered that a quarter of a century has wholly changed the relations of human knowledge, and that the natural sciences have become the chief factors in our modern civilization. Medicine, which once relied upon authority and tradition, is now rapidly seeking for its basis the natural sciences; medical students, of all others, should have a special education in these sciences. So long as a special training is not required as the important part of the preparation for entering upon the study of medicine, so long will the instruction in our medical colleges be incomplete and unsatisfactory. Defects in early training cannot be made good by excellence of professional teaching; mental equipoise, keenness of perception, analytical acumen, and intellectual power of differentiation between fact and fancy cannot be developed after the mind has become dwarfed during its years of plastic growth. To make cultured physicians, our colleges must be furnished with cultured men. The remedy, then, lies more in the hands of the profession than in the colleges. When the profession shall realize their responsibility in this matter, and shall refuse to send to medical colleges, or advise to enter upon the study of medicine men devoid of natural talents, mental discipline, and intellectual power, then will the colleges be furnished with material capable of receiving the instruction which they have to give. In England and on the Continent the higher general culture of the profession has so influenced the mass of medical men that no uneducated man thinks of entering upon the study of medicine. This is the first demand which medical science makes of us, that our *esprit de corps* be more sensitive, that our sense of personal responsibility be more keen, and with a courage born of conviction, and strengthened by the nobility of our calling, we hesitate not to say when occasion permits, "You are not fitted to be a physician; choose some other path of life." When we stand ready as a body to take this position, then, and not until then, will it be possible for our colleges to do that high grade of scientific work which is justly demanded of them. For while we are justly proud, and have ample reason to congratulate ourselves on the many advancements that have been made both in graduate and post-graduate instruction in our city during the past twenty years, and while we are fully abreast, if not in advance, of our sister cities in this matter, we are still far from meeting the demand of scientific medicine—to fully answer its demands. The teaching bodies in our colleges must be placed on a higher plane; they must be separated from the financial interests of the colleges; vacancies in the corps of instructors must be filled by fair competition, thus stimulating the younger members of the profession who desire to made teaching their life-work, to prepare themselves by study and training to fill vacancies in our Faculties as they shall occur. The curricula of our colleges must be so extended and subdivided that not only will a larger number of instructors be needed, and longer sessions required, but what is of far greater importance, that those who teach may, by personal and familiar contact, gain such intimate knowledge of each student and firm control of his mental processes as will enable them to become teachers in the good old Anglo-Saxon sense—to be educators, and not simply instructors pouring out their daily dole of wisdom into unreceptive ears.

[1] Delivered before a meeting of the New York Academy of Medicine, February 7, 1889.

All the facilities for laboratory work, original research, pathological study, clinical observation, and, bedsides, instruction must be systematized and largely increased. In fact our medical colleges must be turned into workshops of scientific medicine, with skilled master-workmen in every department to guide, to lead, and, if necessary, to goad the young apprentice through his daily round of labor until, perfected, he shall go forth fully prepared to take an honorable place among the masters of the land. Not only should our colleges be thoroughly equipped with teachers and appliances for the training of undergraduate pupils, but they should be prepared to give well-trained men, after they have completed their graduate course, facilities for study and experimentation in new fields of investigation.

Our laboratories should be so endowed that scholars of rare ability, who are every year coming to our city for more knowledge, may not only have places to work in, but means to work with.

Why is it, then, that in New York City, the centre of all honorable activity, where wealth groans for an outlet, any institution of human learning should be unable to do good work for the lack of money to do better? Why is it that men of wealth do not realize their great opportunities for wise liberality in this direction, liberalities which will not only shed lustre upon themselves and our city, but will mitigate the sum of human misery as certainly and in many ways far more effectually than our hospitals and charities for the sick and suffering poor? My answer to these questions is, that the medical profession has not, as it should have done, directed the stream of accumulated wealth into this channel. The only appeal untilquite recently has been for means to establish hospitals and charitable institutions, so that to-day hospitals and dispensaries so far exceed the needs of the city that there is actually a premium on patients to fill their wards. Does anyone doubt that if the profession would unitedly urge the great and pressing needs of our educational institutions upon generous-minded men and women they would respond as liberally as they have done for the erection and endowment of hospitals and dispensaries. If educated men and women, by their words and writings, would create a public opinion that a higher education in every department of human knowledge is the only lasting glory of a great city; that mental development is more to be desired than material prosperity, and that next to religion, education is the great corner-stone of our civilization, then would science break the bonds which now bind her, and be able to offer to knowledge-seekers who come to us from every portion of the civilized world equal facilities for growth and development as are at present furnished by the centres of learning in the old world. History tells us that the greatest glory of ancient cities, long since buried in ruins, was their universities and lyceums, founded, reared, and fostered by the patronage and intelligent generosity of wealth and power. It is hardly possible to believe that this great city will much longer remain uncaring and unconscious of her greatest glory. The noble gifts which have been made during the past few years to educational institutions, and especially to medical colleges, inspire the hope that the stream of emotional benevolence for the sick and suffering is being turned into intellectual channels for higher educational needs; and may we not believe that in the near future this city shall produce a class of medical men of broader culture who shall enter on their life-work from a higher plane, carrying with them to the couch of suffering better skill, greater devotion, and a more comprehensive realization of the nobility of the work which they have given themselves to? In this connection there is need of the establishment of scholarships, fellowships, and independent lectureships which shall enable scholars of limited means to engage in scientific work. It is a part of history that, as a rule, the most faithful and efficient scientific medical work in this city has been done by men who in their earlier professional life had only such opportunities as they made for themselves, who were hampered, often almost to the verge of despair, by their lack of means. While appreciating most fully the value of adversity in developing character, I believe it may be carried too far, and that many stewards of idle millions will one day give an account for their failure to supply abundant means whereby brilliant men may be enabled to develop their full powers for the benefit of science and the common good. There should also be created a public medical opinion which shall cause scientific attainments to become so much more honorable than mere professional success, which so often depends on social rather than mental powers, as to induce young men of wealth and intelligence to devote their lives to study and research. Such work might well be done in connection with our colleges or under the auspices of our medical societies. If there were twenty such places of work to day I am confident they would be quickly filled by enthusiastic and intelligent workers, and who can estimate the amount of good that would be done each year, and the great influence it would have in unveiling the obscurities which surround so many of the vital problems now pressing upon us for solution in almost every department of medicine.

Another need of scientific medicine in this city in common with that of our country, I may say of the whole world, is a higher standard of medical literature. The American spirit of so-called enterprise presents no more deplorable manifestation than in the development of our medical literature. Before entering upon its criticism, however, let me say, that no one appreciates more than I the value of the work of many faithful and conscientious laborers in this field—laborers whose writings are the expression of crystallized thought and experience, whose patience never fails, who know no self but only mankind, and who, with a supreme reverence for knowledge and truth for its own sake, are devoting their lives to its development. It is because I recognize the power and greatness of such lives that I feel impelled to offer words of criticism on the redundancy of the medical writings of these latter days. The first fault which I would name is vain repetition, such as the heathen use, and a lack of original thought. Our medical journals are filled with articles that show haste in their preparation and a lack of careful consideration in their statements; positive opinions are given, unsustained by reliable data or extended observations; theoretical conclusions are put forth as established facts, and not as questions demanding experimental answers. It were almost a work of supererogation to demonstrate to this audience that our medical journals too often publish articles that contain not the faintest trace of an idea which is not familiar to every student of medicine. So-called original articles, clinical lectures, reports of special methods of treatment, all repeat the well-known facts that are found in every "Student's Compend," until we despair of finding the little gold among so much dross. To what shall we look for the cause of this?

First: A mistaken idea among the younger members of the profession. An idea for which many of us whose heads are silvering are in part to blame. The eager, ambitious young man, fresh from the hospital, filled with his own knowledge and exuberant life, imagines that the road to fame and wealth lies through the columns of the medical press, and that all who have once seen his name at the head of an article remember it as though it were the writing upon the wall, and will immediately seek his services in consultation. Too often his ideal is given a halo by some older man, who says, Write something for the journals, write often, and let the profession know you. Let us confess this in garments of penitents, and in a more royal spirit let us seek to inspire the younger members of the profession with higher ideals which shall foster in them the spirit of personal achievement, shall develop a pride in quality, not quantity, of mental products, and that praiseworthy modesty which is content to learn until it is competent to teach.

The story or legend of that German savant, who, after a life devoted to the six cases of the Greek noun, mourned upon his deathbed that he had not confined himself to the dative case alone, comes to us like a fairy tale, or the record of an insane asylum. Yet let me tell you within that story, be it fact or fancy, lies the secret of noble achievement of human progress, the essence of the expanding, perfecting life of scientific work. It shows the soul capable of comprehending the infinite possibilities of science, and the self-forgetting ambition which can devote itself to the accomplishment of one thing worthily, whose sufficient reward is in the consciousness of having done faithful work.

When medical writings shall be filled with this spirit a year of the journal medical literature of the French, German, and English-speaking people can no longer be condensed into five small octavo volumes.

I mention as the second cause of medical redundancy the speculative interests of medical publishers, financial necessities of unsuccessful physicians, and conceit of self-appointed authorities. Each of these offers excuse for the establishment of a new medical journal, and another waif is born to feed on patent foods and peptonic mixtures. The doors are thrown wide open, and all aspiring young authors invited to enter without cost, where fame is found at every turn.

Gentlemen, I appeal to you, are these the hands by which our noble science shall be upheld; are these the spirits to suffer and endeavor to work for a life, if need be, that one new truth may be added to our store? They bring but broken stones and rotten beams, which are not worthy a place in our temple of science, whose walls bear polished tablets to the memory of men who labored for truth, not titles; for science, not self; for mankind, not money; for love, not lucre. As one enters upon an analysis of these requirements of higher medical culture and the demand of scientific medicine, he soon finds the essential element of each crystallizing into a single form about a single point, and realizes that the fundamental defect, the one first cause of the established fact that medical science has failed to keep pace with her sister sciences in this country, is a lack of high ideals among the mass of the profession; too often, also, among those who are justly its leaders. As artisans we yield the palm to none; when science passes into art we seize every weapon it offers, and wield them against the common adversary with such fearless force and skill as to cause even the forgers of these arms to confess our greater skill. But in the fields of pure science we still sit at the feet of the old world, and in our secret heart, at least, confess we are as yet hardly competent to be even critics of its teachings. As a body, we have yet to learn what scientific work means. That practical spirit and Yankee ingenuity, born of adversity and developed by opposition, which have made us the foremost nation on the globe in all that tends toward material prosperity, like the unfolding of a century plant, are the very elements that check, nay, forbid, the growth of pure science. Every other science but ours tends directly toward the production of material results, toward the production of wealth. It is America that has seized Jove's thunderbolts and bounded them in the service of mankind; has made them meek and patient servants, that do our bidding as does the muzzled ox, because the harnessed lightnings draw out the golden shekels. But he who seeks to bind in scientific laws the lightning of the mind, or trace the labyrinth that lies 'twixt cortex and medulla, must never hope to see the gleam of gold; he feeds alone upon the thought that generations yet unborn will one day know the worth of all his patient work and will rise up to call him blessed. It is not to be wondered at that the medical profession has been borne along with the multitude and has been given over to the search for patients and fees rather than bacteria and ptomaines. But it seems to me that the time has come when not the few (and all honor to these few who have been the advance-guard) but the many should be given higher ideals; should be lifted to that higher plane where intellectual work is valued for what it produces new. No man surpasses his ideal, and before we excel in pure science our ideal must be one of intellectual power, and not of material prosperity. But such ideals are not of individual creation, like cathedral towers, to be raised above contamination of earthly things into the clearer upper air, they must be the product of many hands and many minds—of united and concerted action. This seems to be the mission of our Academy, to be both the artist to conceive and form, and the guardian to preserve and sustain an ideal medical spirit of the profession of this city and our country. No great conflict is ever waged successfully without one controlling mind. We have in this city many strong minds, but they are like an army of undrilled recruits; much of their work is rendered useless because unconcerted; often it is simply repetition which might have been avoided, and the general result is weakened in authority and lessened in value because often incomplete and defective.

Medical men need a "clearing-house" as much as do the banks; they need an exchange where each may bring the results of his work, and learn what his fellow-worker may have done in way of support or opposition, and most of all we need a controlling spirit, a head to plan lines of attack, to bring together the scattered forces for their own and the general good. It is my ambition to see the Academy occupy this position, standing as the centre about which all the workers of our city may gather, giving them in return loftier ideals, inspiring in them stronger ambition to be truly scientific men, while it not only encourages, assists, and stimulates them to better work, but also rewards every praiseworthy achievement. In order that our Academy may thus become the centre of the scientific activities of the entire profession it must have a suitable home—a building that shall furnish accommodations for a large and well-selected library, with reading-rooms, and commodious meeting-rooms for all the medical societies of the city. Such a building the Academy is now struggling to establish. Our organization is no longer an experiment—it has passed successfully through the perils and contentions of its infancy, childhood, and youth, and is now entering its full manhood. The spirit of devotion to a high scientific purpose which actuated its founders, and which has always been one of its characteristics, has caused it from year to year to grow in professional esteem and public confidence, until it may truly be said that it is the strongest power in this city for the advancement of scientific medicine. It has outgrown its building accommodations, its library can no longer find shelf-room, and is constantly exposed to destruction, the building not being fire-proof. Its Sections crowd upon each other to such a degree that their work is crippled; it is unable to do the good work it might do on account of its limited space. The need of a new Academy building, with a fire-proof section for our library, is an urgent one, and if we shrink from our responsibilities in this matter, we shall prove false to the legacy received from those who gave so much of labor and sacrifice to bring it to its present growth and usefulness. As we recall the many distinguished men with whose lives it is interwoven, and who did so much to make it a centre of medical thought, are we not stimulated to greater endeavors, to greater sacrifice, to an energy akin to enthusiasm which never rests until it has realized the great thoughts and possibilities which gave it birth? What has already been accomplished gives assurance of ultimate success; never before have its Fellows been so united in opinion as to the immediate necessity of a new building. The Academy funds, with the pledges of money which have already been received, leave little doubt that, in the near future it will have a new building in every way adapted to its scientific work. To the accomplishment of this let each Fellow give himself heartily, not only by contributing himself, but by interesting his friends and

gaining donations from them, for, as has often been stated, each citizen is personally interested in everything that shall advance medical science. If the profession in this city can have free access to a large and well-selected medical library, with a scientific centre where they can contribute new observations, new facts, and new methods of treatment, subject to the criticism and judgment of their peers, and where each one shall criticise in a scientific spirit the offerings of others, the public will receive in their medical attendants greater skill, more careful and intelligent observation, and, as the medical profession as a body shall rise to a higher plane of scientific worth, the sick will turn less frequently to empirics for relief in their hours of suffering and in their struggles with disease; the sanitary safety of our great city will no longer be committed to unprofessional and unscientific hands, but will seek the protection of a broader-spirited and more enlightened profession, who, by wise councils and more practical methods, shall protect it from the ravages of those diseases which, it is being demonstrated each year, may be limited, if not altogether prevented, by the new and more advanced methods which are being formulated by a broader and more perfect sanitary science.

It seems hardly possible that intelligent wealth, whether selfish or broad-spirited, with such and kindred thoughts before them, will long hesitate to furnish the required means not only to build a new Academy building, but for so increasing its library that it shall become the central attraction for scientific workers in our city and the whole country.

But, Gentlemen, I would not speak only of the material interests of the Academy, of its building and library, I would congratulate you on the broader spirit which is being developed in its membership. We are each year becoming more tolerant toward the opinions of others. The links which bind together junior and senior members of the profession are being forged with greater strength. The jealousies and intolerance of cliques is fast giving place to liberality and good-fellowship. The questions now asked concerning a Fellow are not of his birth or of his school, but has he done good work, and is he likely to do more? We rejoice in no medical politics or medical ethics, a scientific atmosphere is pervading everything that is being done. Men who heretofore have stood aloof and who have done their work in special societies are coming into its Sections and making them effective. This centralization should go on until in the Academy would be found all the best thought and the best work of the entire profession. Let it become the fountain from which shall flow the purest streams in every department of medical science, a place where the young and old, the savant and the young enthusiast shall cross swords in that spirit of deference which one scientific worker is always willing to accord to his fellow.

The Committee on Drug Adulterations of the Missouri State Pharmaceutical Association desires to ascertain, as far as possible, how near the official substances dispensed in the State conform to the requirements of the United States Pharmacopœia. It requests each druggist in the State to select one official substance and procure a sample in his vicinity, and apply to it the pharmacopœial tests. Reports of work done for the committee will be tabulated and read before the Association at the next annual meeting, at Pertle Springs, June 18, 1889, and full credit will be given to persons having performed the work.

A Low Temperature.—Dr. Waugh showed at his clinic a lad, seventeen years of age, who had had a temperature during the preceding week of from 92.6° F. to 97.5° F. The temperature of 92.6° F. was verified by four thermometers, and was the lowest, Dr. Waugh said, that he had ever known a human being to have and survive.—*Medical Times* (Philadelphia), December 15, 1888.

MEDICAL EXPERT TESTIMONY.

Anniversary Address Delivered before the New York State Medical Society, February 5, 1889.

By SAMUEL B. WARD, M.D.,

Albany, President of the Society.

Gentlemen of the Medical Society of the State of New York: The laws of this country, and the practice in our criminal courts differ in some fundamental respects and in many details from those existing under other civilized governments. With us the accused man is entitled to and, in the vast majority of instances, secures every possible opportunity for defence. He cannot be compelled to give evidence which would tend in the remotest degree to criminate himself; his wife may not give evidence against him; his physician and his legal adviser are not permitted to divulge any information which they may have received in their respective professional capacities; he himself is always supposed to be innocent until he is proved guilty; and the jury are charged to give the prisoner the benefit of every reasonable doubt. If the accused has means he can employ what legal counsel he may select; should he be penniless the court assigns to some lawyer the duty of defending him.

Undoubtedly the practice of having counsel for the defence originated in the manly desire in our race that no injustice should be done to a man ignorant of the law. At the present day it is not considered at all dishonorable for most eminent counsel to espouse the cause of a prisoner whom they know to be guilty; and by carefully concealing evidence of the existence of which they are perfectly aware; by confusing and embarrassing witnesses; by taking advantage of every legal technicality; by the weight of their erudition and personal character; and by their persuasive eloquence with the jury they frequently succeed in making the worse the better cause appear. Their position is far different from that of the witness on the stand, who is supposed to tell the truth, the whole truth, and nothing but the truth. All this procedure may or may not be in strict accordance with the highest code of morals—may or may not, in the long run, be productive of the greatest good to the greatest number. It is certain that we as medical men have no more interest in it than any other body of reputable citizens.

But in a majority of criminal cases questions arise which no layman can answer, questions about which even members of our own profession may differ in opinion; the lawyers on both sides take counsel with the doctors, and the physician called to the stand to express a professional opinion becomes known as a medical expert.

There are other classes of cases, it is true, in which expert evidence becomes necessary, as in determining the strength of material used in constructing a bridge, a ship, or a piece of machinery. But every science is exact just in proportion as mathematics can be applied in working out or demonstrating its results; and, unfortunately for us, with the single exception of errors of refraction, mathematics does not come to our assistance in any degree worth mentioning. The capacity of a piece of Bessemer steel to resist a strain, longitudinal, lateral, or by torsion, is known with perfect accuracy within certain pretty narrow limits; it can be accurately expressed in figures; and it is not possible for truthful experts to make statements concerning it greatly at variance with each other. But the phenomenon with which we are called upon to deal are of an entirely different order; can rarely become the subject of experiment; are extremely complex in their nature—so complex that to isolate the component elements and prove how much influence is to be ascribed to each, is, up to the present time, simply impossible; it remains a matter of judgment and opinion. Nor is this condition of things the result of any lack of diligence on our part, or of native ability on the part of those who have in all the past ages applied their best energies to the study of medicine. It is simply inherent in

the complex nature of the problems presented to us for solution. Hence it is that medical experts may honestly differ from each other more widely than those in most other professions.

If, however, questions of law or theology could be submitted to the expert on the stand as those in medicine are, it would be easy for counsel to procure opinions more radically at variance than those expressed by members of our own profession. The opprobrium cast upon us is, to a certain extent at least, undeserved and unjust. In support of this statement we have only to note how counsel wrangle with each other over many points of law arising in every case that is argued; how the decision of the lower court is on appeal alternately reversed and affirmed in each succeeding higher one until the court of last resort is reached; and how even the highest courts in the land have at different periods rendered decisions incompatible with each other. Or imagine for a moment the divergence of opinion which would become apparent if a Materialist, a Unitarian, a Methodist, and a Roman Catholic were called upon the stand to express their views concerning justification by faith, the divinity of our Saviour, the doctrine of eternal punishment, or even the existence of a future state at all. And yet it is a matter of history that these men have had such profound faith in the eternal righteousness of their convictions that they would rather burn at the stake than abate one iota thereof. We can safely promise entire unanimity of opinion on all points as soon as this blissful state is attained by either the lawyers or the theologians.

The lawyer engaged on one side or the other of a criminal suit finds that medical points are necessarily to be raised, or thinks that they may be raised with advantage to his cause. We all know that almost every important case occurring in our daily practice presents some one or more features that are unusual, are rare, are sometimes almost inexplicable, and criminal cases are no exception to the rule. Counsel therefore looks about for some one of our profession to assist him. He presents his statement to a medical man and finds that his opinion is not of a nature to serve the purpose he has in mind. He goes to another and another, until finally he finds one who entertains opinions to suit him, or approximating thereto, and this one he engages to appear on the stand as an expert. One defect in the present law is that this man may be subpœnaed to appear in court at an inconvenient hour and distance, to the disappointment of his own patients, to the neglect of any or every other professional engagement, and kept waiting there an indefinite period of time for the paltry remuneration of fifty cents a day and eight cents a mile for travelling expenses. Such instances are of course exceedingly rare, and, as a rule, the medical expert is fairly compensated. In some cases the fee is agreed upon beforehand; in a few an effort is made to have it dependent upon the issue of the case—a condition which cannot be too strongly reprehended.

I believe that medical men, almost without exception, when they go into a case, fully intend and mentally resolve that they will not take sides; that they will make every effort when on the stand to live up to their oath and to be as impartial as the judge upon the bench. But even the judge does not always succeed in not taking sides, and the doctor, like the judge, is but human. Moreover, he, unlike the judge, has, in private at least, expressed an opinion, and he certainly wants to see that opinion prevail, primarily because he believes it to be the correct one, secondarily because it is his. In all callings, from religion to politics, every man innately rejoices in convincing others of the correctness of his views. Moreover, the lawyer is, collaterally at least, and in many cases primarily, working to win because his client is paying him. Had he been paid by the prosecution instead of the defence he would have taken an entirely different view of the case. He would not in either event tell an untruth; but he would under different circumstances attach very different values to the same item in evidence; would entertain very different opinions as to the credibility of witnesses; would cite another set of authorities and of precedents; would express to the jury an exactly opposite opinion and call upon them as good men and true to render a diametrically opposite verdict. The unfortunate medical expert is also human, subject to like temptations and influences as other men. He knows that the public puts him on a different plane from the counsel, and expects him to tell what he believes to be the exact truth, no matter whom it may help or hurt. But then there are many points about which a man may be in doubt; about which he may entertain one belief at one time in his life and another at another—I had almost said that he may believe as he chooses to believe—points that are not matters of fact, capable of demonstration, but absolutely and wholly matters of opinion. And he knows that as the case now stands the side from which he accepts payment expects him to believe and express opinions tending in a certain direction.

Moreover, it is certainly true that there are a few men in our profession who entertain opinions differing widely from those of the large majority. These opinions, expressed in private conversation or in medical meetings, result in very little harm, because they are estimated at once at their true value. But the holders of such opinions are precisely the men whom the counsel in a desperate case is desirous of retaining. By them he can show to the jury how uncertain and divergent medical opinions are, and throw doubt upon the reliability of the evidence produced by the other side. For instance, in a rural community I have heard a physician, whose fine personal appearance, army experience, large and successful private practice, and gray hairs gave weight to the minds of the jury to every word he uttered—every man on the jury knew him by sight and reputation, and a majority of them personally—I have heard this physician say that, in his opinion, "any man who used any splint in the treatment of any form of fracture was guilty of malpractice." Such monumental nonsense as this, is, of course, very rare; but the incident serves well to illustrate the abuses to which the present system of obtaining and using expert evidence is liable.

The physician selected as an expert considers his case carefully; he reads up the various authorities, paying, of course, considerable attention to those whose views agree with his own, and mentally remarking what sensible men they were, while the impression formed of those who differ from him is not nearly so complimentary. He looks up the records of similar cases in medical journals, and finally goes on the stand well prepared to answer truthfully the questions previously arranged to be asked him on the direct examination. During this investigation of the case it is sometimes curious to observe how the expert's opinions will become strengthened in the direction of the side which he has espoused. Without any real additional arguments having been brought to light he will incline to give more and more weight to facts which seem to favor his view, and become more and more inclined to make light of, or even to ridicule, facts or opinions which militate against him. He often ends by being honestly persuaded that there ought to be no manner of doubt on points which are in reality very doubtful and which at the outset he willingly admitted so to be.

When the expert goes on the stand he is first questioned by the lawyer on whose behalf he appears. The questions are hypothetical ones, supposed to be based on the facts proven on the trial. As a rule this is fairly done, and the expert has no difficulty in giving honest, straightforward answers.

The direct examination completed, the counsel for the other side takes the expert in hand and his trials begin. In some cases, in the majority of cases perhaps, he receives perfectly fair treatment. The cross-examiner simply endeavors to bring out all the weak points in his view of the case, to show how very weak they may be; that they are matters of opinion and not of fact; that other

honest men may take a different view of the case, and that an entirely different theory may not be wholly without foundation. Even though the treatment he receives be perfectly courteous the ordeal is a trying and disagreeable one. While he is honest and frank in his answers he must be very cautious in the wording employed, resting assured that every slip will be taken advantage of, and every response stretched to its utmost limit of construction, even if it be not entirely twisted out of its original meaning, when the case comes to be summed up before the jury.

At other times, and especially if the counsel is conscious of having a bad case, the expert may be treated very differently. Instead of its being assumed that he is a gentleman who has taken the stand for the sole purpose of giving information of a technical character and telling the exact truth, it is assumed that he is there for the purpose of aiding the side which called him, and sometimes it appears to be further assumed that he is scarcely hampered by the ownership of a conscience; he is treated as though it was known that he was lying, and every effort must be made to catch him at it. Questions are asked which cannot be answered truthfully without conveying an entirely erroneous impression to the jury; a categorical answer is insisted upon, when such an answer without an explanation is virtually a falsehood; questions are asked which are capable of several different subsequent explanations; others which have, in the form in which they are put, absolutely no meaning at all. On one occasion I recollect a lawyer's laboriously going over all the organs and tissues of the body from the scalp to the toe-nails, and being informed by the medical expert that, in his opinion, no one of the organs was the subject of pathological change. He then inquired if this man was sound from head to foot what ground he had to claim damages. The answer was that the functions of the nervous centres were so deranged as to prevent the claimant from pursuing his vocation and supporting his family. The expert was then requested to state to the intelligent jury precisely where these "functions" were located and what they looked like. By this time the expert was so thoroughly annoyed, angry, and disgusted that he declined, for the moment, to answer any more "stupid" questions—and woe betide the expert who for a single moment loses his temper.

Sometimes the "stupid" questions are put for the very purpose which was reached in the instance quoted, of confusing, annoying, and angering the expert, or of catching him in apparent contradictions, the explanation of which, to the average layman on the jury, is always tedious and often impossible. At other times the questions are not intentionally "stupid," but are so simply by reason of a lack of medical knowledge on the part of the counsel propounding them. Your President last year, in his inaugural address, speaking of medical experts, said: "Their testimony is often of little value, on both the direct and cross-examination, from the fact that the questions which they are called upon to answer are formulated by lawyers who have little medical knowledge; or if, as sometimes happens, a physician is employed to assist a lawyer, the lawyer not understanding the real import of the questions which his Mentor may suggest, perplexes the witness, and too often places his assistant in an undignified position, so that medical-expert testimony often disgraces our profession." When a lawyer is asking questions prepared for him by his medical expert for use in the examination, it is not uncommon to see a well-laid train of reasoning entirely destroyed by a single unexpected answer, when, in point of fact, the answer given was more favorable to his view than his medical friend had dared to expect or hope for, and the only trouble was that the counsel, not knowing enough of medicine to take advantage of it, abandoned his argument just when success was within his grasp.

While medical experts are, as a rule, men of large experience in the practice of their profession, each of them must, on some occasion, have gone on the stand for the first time. The position is then to him novel and embarrassing. He is unfamiliar with the rules of the court, the audience is a strange one, and the counsel is not averse, if it suits his purpose, to take advantage of these circumstances. Sometimes the lawyer will undertake the process of brow-beating the witness, repeatedly reminding him that he is under oath; cautioning him to be careful about his statements; gesticulating violently; and sometimes succeeds in getting the young man, if he is at all bashful, in such a condition of mind that it is impossible for him to recollect facts with which he is perfectly familiar, or to couch his answers in appropriate language. A favorite device with some is to ask the expert concerning all the possibilities of the case, not taking at all into account the probabilities. The timid expert is, perhaps, unwilling to admit a possibility, fearing that his admission will be afterward misrepresented to the jury as expressing his opinion of what was a probability. Under such circumstances I have repeatedly heard good, honest, careful men deny the possibility of an occurrence which, in their cooler moments, and when they did not fear that their meaning would be misinterpreted and misapplied, they would freely admit. Indeed, since it is a matter of record that an iron tamping-rod, five feet long and three-quarters of an inch in diameter, has passed vertically through a man's skull, scattering his brain more or less extensively over a forty-acre lot, the patient living more than twenty-five years afterward, and the accident resulting in no great permanent disability other than the loss of sight of one eye, it is difficult to swear that anything is impossible, and yet an infinity of possibilities are not in the slightest degree probable.

One of the most unfortunate results of this condition of things is, that it is frequently impossible to get the most substantial and reliable men among us to go on the stand under any circumstances, or for any consideration, and their places are sometimes taken by ambitious men, with more assurance than mental balance or experience, who see an easy way of attaining a notoriety which they mistake for well-founded fame, and whose main object is to be on the winning side, if that end can be obtained without stretching their consciences beyond the breaking-point.

If the present system of obtaining medical expert evidence resulted simply in the annoyance occasioned to medical men, or the disgrace brought upon the profession by an apparent or real difference of opinion expressed on the stand, there would be great cause for complaint on our part, though we could not expect much sympathy from others. But it is respectfully submitted that, above and beyond this, the present system does not tend to bring out the truth in the shortest and clearest manner; in fact, in many instances is believed to have resulted in a miscarriage of justice. Almost any lawyer of large experience in the conduct of criminal cases will tell you that he has been sometimes ashamed of the use which he has made of expert testimony, or else will gleefully chuckle over it. This matter was brought to the attention of this Society as long ago as 1879, when, in his anniversary address, Dr. Roosa so eloquently spoke of the evils attendant upon the present system.

Many remedies have been proposed, but up to the present time no action has been taken toward applying them. Dr. Loomis last year proposed that the questions to the expert should be framed by a medical man employed or appointed for that purpose. This would undoubtedly help matters to a certain extent, but would, after all, fall far short of accomplishing all that might be wished for.

A well-known judge of the Supreme Court has suggested that in each judicial district, a physician of eminence should be appointed by the court, whose duty it would be to appear as expert in every case where his services were required. This man would, upon the stand, be free from all the bias which arises from the fact that

he is paid by one side or the other, and a great advantage would, without doubt, be gained. But he would be subjected to all the annoyances and vexations of the examination, and the plan would be manifestly impracticable on account of the varied acquirements demanded of the expert in different classes of cases. The same man can scarcely be expected to be an expert in chemistry, surgery, medicine, and obstetrics, and, while the expert would be free from partiality toward either side, his evidence would probably be entirely satisfactory in only some one class of cases. Moreover, there are few medical men who would be willing to be placed in a position where the expression of their individual opinion virtually results in the imprisonment of a fellow-being for a term of years, or launches him into eternity. It is scarcely probable, again, that this plan would meet with the approbation of the legal profession, who would, naturally, desire that the views of each side should be presented in their best light.

In most cases where medical expert evidence is required at least two physicians are called to the stand, and in many cases a half-dozen. The remedy which we would suggest would be, that under such circumstances a board of three experts should be appointed by the court; one on the suggestion of the counsel for the defence, one nominated by the counsel for the prosecution, and a third by the court itself; that these experts should be paid by the court and the charge divided equally between the two sides; that to this board of experts should be submitted in writing the questions involving medical matters; that the answers should be submitted in writing and sworn to, and that medical witnesses should not be required to go upon the stand. In the event of the failure of the board to entirely agree a minority report might be admitted, and if each side desired to be represented by two or three experts instead of a single one, there would be no objection to such a course.

The adoption of this course would certainly result in obtaining from medical experts opinions free from the bias which arises from the expectation of pecuniary reward from either side, the unseemly antagonisms between the expert on the stand and the cross-examining counsel would be avoided, and the ends of justice be more speedily and surely attained.

THE TECHNIQUE OF VAGINAL HYSTERECTOMY.[1]

By JAMES B. HUNTER, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK.

In order that a capital operation shall commend itself to the profession two facts must be demonstrated in regard to it: First, the immediate mortality from the operation must be small; second, the results, immediate and remote, must be such as to show that the benefit to the patient is sufficient to compensate for the risks incurred. In regard to vaginal hysterectomy, ample evidence as to the second point has already been furnished by foreign writers; most recently by Secheyron. It may be assumed, therefore, that vaginal hysterectomy in suitable cases of malignant disease of the uterus has taken its place among the justifiable operations. My purpose is to deal chiefly with the first point, and to show that the operation may be so performed as to render the mortality very small. If it can be shown that the more radical operation entails but little more risk than does a high amputation, few surgeons would hesitate as to which operation should be performed. It may be mentioned here that in all capital operations statistics based upon a small number of cases have very little value. The more difficult the operation, the greater will be the mortality in the earlier operations of every surgeon. Experience counts very largely in such operations as vaginal hysterectomy.

[1] Read at the meeting of the Medical Society of the State of New York, February 5, 1889.

The immediate dangers of this operation are shock, hemorrhage, peritonitis, and septicæmia. Many of the operations reported have occupied a long time, some of them more than two hours, and some nearly four. In such cases shock is very apt to follow. Rapidity may be considered an important element in all serious gynecological operations. A study of the cases of hysterectomy reported by the German surgeons, notably Martin, will show that the cases in which the patients succumbed to shock were those in which the operation was prolonged from one and a half to three hours. Much of the time lost is occupied in securing the important vessels by ligature. Pean certainly conferred a great benefit on surgery when he demonstrated the application of the hæmostatic forceps to vaginal hysterectomy; and it may be noted here that his claims are prior to those of Richelôt. I shall attempt to show that, both theoretically and practically, the forceps in this operation have a vast advantage over any form of ligature. I have now used the forceps for the principal vessels in eleven cases of vaginal hysterectomy in the New York Cancer Hospital, with two deaths, one from acute Bright's disease, and one from secondary hemorrhage in consequence of an imperfect forceps. In eight cases I have used no ligatures of any kind. The method of using the forceps will be made more clear if the other steps of the operation are described somewhat in detail.

The first steps of the operation are substantially the same whether the forceps or ligature is to be employed. One assistant should stand on the right of the operator, and on him devolves the chief responsibility. A second assistant, or an experienced nurse, is seated on the left of the operator, to hold the speculum and do anything else that may be necessary. The instruments are placed on a low table, within reach of the operator and his chief assistant. One nurse is assigned the sole duty of caring for the sponges. I prefer to have the patient on the back, brought well down to the edge of the table, the limbs being flexed and supported by assistants, or by the crutch, as in operations on the perineum. The largest Sims speculum is then introduced, after thorough irrigation with a two per cent. creoline solution. The uterus is then drawn down by Bernay's uterotractor. By pushing it back in place the line of union between the vagina and cervix is made clear, and at this line the incision begins, the uterus being first drawn downward and backward. Broad retractors are useful in some cases for lateral separation. With a curved, blunt-pointed scissors the bladder is carefully separated from its attachment, a sound being kept all the while in the bladder, and manipulated by the chief assistant. The finger is then passed up until the peritoneum is reached, when that part of the operation is abandoned, the peritoneum not having been opened. The uterus is then drawn forward, and a similar dissection is made on the rectal side. It is not important whether the anterior or posterior section is made first, but it is easier generally to do it in the order described. The next step is the separation of the lateral attachments. It is well to cut very cautiously here, and also with scissors, lest the uterine artery be prematurely severed. The peritoneum may now be separated anteriorly, and the finger made to reach the upper border of the broad ligament on one side. At this stage of the operation, I usually pass a strong silk ligature temporarily over the broad ligament, by means of my projecting needle, and can thus control the upper border and draw it down in applying the second forceps. The forceps are then applied close to the uterus, and in such a manner as to include only the uterine artery. The handles of the forceps when properly placed should be tied with silk, to guard against the possibility of their becoming loose. The tissue included in the forceps may then be cut close to the uterus, the operator watching carefully for hemorrhage. A second forceps is then applied higher, and made to include the remainder of the broad ligament and the ovarian artery. The same process may then be repeated on the opposite

side. An attempt may then be made, by seizing the fundus with a large hook, to antevert the uterus. The utero-sacral ligaments usually need to be divided at this stage of the operation, and may be seized with a long forceps before division. It is well to seize *every bleeding point*, artery, or vein, with forceps, some of which may be removed when the operation is complete. According to circumstances, the uterus may be drawn down in the axis of the vagina, or it may be anteverted, or retroverted. The four forceps guarding the important vessels should all be secured by tying the handles, after they are properly applied. The danger of prolapse of the intestines during the operation has been greatly exaggerated. Ordinarily they do not come into view at all. If, at any stage of the operation, the ovaries or tubes are seen, it is better to remove them, using a silk ligature, or, if practicable, a light forceps. The vagina is then lightly packed around and between the forceps with creoline, or iodoform gauze. The use of styptic cotton at this stage is objectionable, as it is very hard to remove, and leaves an ugly cavity. If gauze or cotton in small quantity is passed up high, it should always be secured by strings to make sure of its easy removal. The projecting handles are enveloped in a mass of cotton, and so supported that they cannot drag or cause pain. If there is a sufficient supply and variety of forceps in readiness, ligatures will very seldom be necessary, nor will there be much opportunity for using the cautery, which I have never yet had occasion to employ in this operation. The danger of injuring the peritoneum or intestines is greater with the cautery than with other means. The patient is then put to bed and treated as after any serious operation. The bladder is emptied by the catheter at proper intervals. The bowels are moved on the third day, generally by means of three or four half-grain doses of calomel, in triturated form, given at intervals of an hour, and followed by a saline aperient, usually a seidlitz-powder. The absence of pain after this operation is somewhat remarkable, and morphine or other anodynes are rarely necessary. Light nourishment, as milk and lime-water, milk and Vichy, koumyss, or peptonized milk, is given as soon as the stomach will tolerate it, which is generally from twelve to twenty-four hours after the operation. The forceps are removed after thirty-six hours; those which are applied to the large vessels, being tied, can be distinguished from the others and removed last. It is often necessary to leave in the vagina six or eight, or even ten pairs of forceps. In one case, which did remarkably well, I left fourteen pairs attached. As the instruments give some annoyance by their weight and bulk, those which are attached to the less important points may be removed at the end of twenty-four hours. No force is necessary to remove the forceps, which usually come away almost of themselves as soon as they are unclasped. Sometimes a very slight rotary movement is necessary to detach them. The least important forceps should be removed first, and those securing the large vessels last. When the latter are removed, the gauze is carefully withdrawn, and fresh gauze put in its place. It will be found, practically, that the margins of the peritoneum fall together of themselves and close the opening. No sutures are necessary for the purpose of uniting the edges of either peritoneum or vagina. When the forceps are removed there is generally some discharge, and the gauze is often saturated with a serous fluid without odor. No injections should be used at this time, nor should the speculum be introduced, or any vaginal examination made, without some special reason. A light tampon of gauze is then introduced, unless there is a free or offensive discharge. If proper care be taken there need be no erosion or irritation of the vulva by the forceps. This is a very important point as concerning the subsequent comfort of the patient.

During the first week a light tampon of gauze is introduced once a day to give support to the vagina and to insure drainage. In no one of my cases has there been any hemorrhage whatever after the forceps were removed. No vaginal injections should be given till after two days. There has seldom been any rise of temperature, there has been no peritonitis in any case, and no septicæmia. In some of the cases a large friable mass, the epitheliomatous cervix, has been broken down in the vagina during its removal, but in no case has there been any evidence of infection from that cause. At the end of the first week the discharge becomes very slight, and a digital examination shows a small opening in the vault of the vagina, barely admitting the finger. At the end of the second week there will be felt merely a puckered cicatrix, which in time becomes still smaller and closes entirely. I have never known any fistulous opening to remain. Healthy granulation has always taken place. The patients are allowed to sit up in bed at the end of the second week, and to get up at the end of the third week. One patient left for her home, at a distance, exactly three weeks from the day of the operation. All injections have been discontinued at the end of the third week, and no subsequent treatment has been necessary. When there has been any sign of a recurrence, it has been in the edge of the wound, at a point easily accessible for treatment. In this particular there is an advantage over the operation of high amputation, in which recurrence is not so easily detected, or treated when it does occur. Adhesion of the intestines to the wound has been reported in three cases. It has not occurred in any of my cases, and seems no more likely to occur after vaginal hysterectomy than after an ordinary laparotomy. Every precauti is taken to render the operation aseptic, but on account of the condition of the cervix this is often impossible. There has, however, been no evidence, in any case, of infection from that cause. There has been no prolapse of the intestine, and there has been no case of septicæmia. The evidence has all been in favor of the fact that shortening the operation lessens the danger of shock. The patients who recovered had all a remarkably easy and uneventful convalescence.

It may be safely said in favor of the use of the forceps in vaginal hysterectomy, that they save time, that they are easier of application than the ligature, and that they make more firm and permanent compression. In one case in which I used the ligatures, they did not come away for three weeks, and very much interfered with the process of healing. The forceps also favor drainage at the time when it is most necessary. Their removal causes no pain, and requires the use of very little force. There is less danger of injuring the ureters with the forceps than with the ligatures, as they can be applied more closely to the uterus. In using the ligature on the broad ligament there is always a possibility of retraction, and in the operation in question it is exceedingly difficult to reach the broad ligament when it has retracted. More traction on the tissues is required in applying a ligature than in applying the forceps.

Finally, to the inexperienced operator—and there must always be some inexperienced operators—the forceps offer a much better prospect of success than the ligature, as less skill is necessary for their application.

I have used a variety of forceps, including those of Richelôt, but now prefer a strong Tait's forceps to any other. I am satisfied that it is better not to attempt to include the whole broad ligament in one instrument. Two small forceps are better than one large one, and are much more easily applied.

The Laborer is Worthy of His Hire.—In Los Angeles, Cal., no one is permitted to practise medicine until he has signed a fee bill and takes oath that he will abide by it. This prohibits him from charging less than a certain rate, but does not limit him in placing an estimate on his own services. The custom is to collect at the time the service is rendered.

THE EARLY RECOGNITION OF CANCER OF THE CERVIX UTERI.

By HENRY C. COE, M.D.,

NEW YORK.

Some apology seems necessary for introducing a subject on which so much has been written. The writer, through his connection with the New York Cancer Hospital, has had an opportunity of studying the histories of many incurable cases, and, almost without exception, the patient has stated that she did not know what was the matter with her until the disease had made such inroads that a radical operation was out of the question. Her physician had not recognized the existence of cancer until it was too late. It did not seem as if the higher education of the general profession in regard to gynæcology had been extended to the early recognition of malignant disease of the uterus. If this was the case we would not encounter so many inoperable cases. The writer would not be understood as harshly criticising general practitioners, since they were often prevented from making a vaginal examination by considerations of an ethical character, which did not stand in the way of the specialist—especially the opposition of the patient herself.

The writer proposed to confine himself strictly to the practical side of the subject—avoid all disputed points in pathology. He desired at the outset to call attention to certain popular errors with regard to the symptomatology of malignant disease, all of which he had repeatedly seen confuted in both hospital and private practice. The advanced age of the patient, "cachexia," pain, hemorrhage, and offensive vaginal discharge were regarded as pathognomonic of malignant disease. As a fact, over twenty per cent. of the patients were below forty, and they frequently presented every evidence of robust health, even in cases of advanced disease. Pain was a later symptom, and was often notably absent. Hemorrhage was often not sufficient to deserve the name, and very rarely threatened life. The foul, watery discharge, so often alluded to, was sometimes absent, even when the ulceration was quite extensive.

The most common symptom noted in connection with incipient epithelioma of the cervix was bleeding. This might be merely an increase of the menstrual flow (especially in women near the climacteric), but the most significant form was that called by the Germans "atypical" hemorrhage, *i.e.*, a slight show at irregular intervals between the periods. It might be simply a pinkish discharge. This was especially significant when occurring in women after the climacteric. Bleeding after coitus was always significant, and called for a prompt examination, even if no other symptom was present.

A profuse leucorrhœa in a woman who had passed the climacteric should awaken suspicion, though no odor could be detected. Pain, of the severe lancinating character present in the advanced stage, was absent. Vague shooting pains in the pelvis in women previously free from them were of suspicious import. These pains may extend down the thighs, and be mistaken for sciatica (as in a case under the writer's care).

The symptoms mentioned should lead the attendant to make a vaginal examination, when he will find the cervix usually lacerated, large, thickened, and having peculiar nodules along the edges of the everted lips. At a somewhat later stage the cervix will feel more like a mushroom. Firm pressure is not painful, but may cause slight hemorrhage. No odor will be noted on withdrawing the finger. The uterus is somewhat enlarged, but movable, and there are no evidences of perimetritis. As seen through the speculum, the cervix may present the ordinary appearances seen in erosion (the boundary line between which and cancer is often determinable only by the microscope). The ovula Nabothi are usually present in erosions, says Schreider. If there is a sharp separation between the diseased and healthy spot this is suspicious. The cancerous nodules appear as glistening, yellowish nodules, elevated above the level of the healthy tissue. General hardness of the cervix, in connection with extensive erosion, was always a sinister sign. In case of doubt, excise a wedge, including the deep fibro-muscular tissue, and examine microscopically. In the case of a simple erosion there was loss of surface epithelium, and glandular hyperplasia; atypical cell-processes, dipping down into the tissues, or groups of epithelial cells, showing an alveolar arrangement, pointed to malignant degeneration. How difficult the diagnosis of incipient cancer might be was shown in the case of the late Emperor Frederick. In certain cases the pathologist would be unwilling to give a positive opinion, simply calling them "suspicious." The indications for treatment in such cases were sufficiently clear. The prognosis in such cases depended upon the early recognition of the trouble. In the case of incipient cancer absolutely confined to the cervix, there was no reason why the patient should not be completely cured by excision or high amputation of the cervix, which should be tried before resorting to complete extirpation. The writer favors entire wedge-shaped excision of the cervix in every suspicious case, whether really malignant or not. It was not sufficient to simply repair the laceration. Patients with extensive erosion were always in danger of the trouble passing the boundary between the benign and the malignant. The diseased tissue should be thoroughly removed. Local applications, caustics, etc., were not to be thought of; the cervix must be removed with scissors. In this way many lives would be saved or prolonged, which are now lost, either from extension of the disease or from too heroic procedures at removing it, which are resorted to too late.

A CONTRIBUTION TO THE SURGERY OF THE SPINE.[1]

By ROBERT ABBE, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK; CONSULTING SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED; PROFESSOR OF SURGERY, POST-GRADUATE SCHOOL AND HOSPITAL, NEW YORK.

The surgery of the spine is one of the new chapters soon to be written, from which much may be expected. As yet, however, so little work has been done or published that statistical tables upon the subject are untimely and of little profit.

It should be a surgical axiom that every case of operative interference should be published, and I shall therefore present concisely, for our study, two cases that have recently come under my care, deducting such practical lessons as may be deemed important. I have the pleasure of showing you the patients themselves.

Extra-dural tumor of spine—Paraplegia complete—Operation—Recovery.—The first case is a man aged twenty-two, who was in excellent health up to January of last year, when pain in his back was his earliest symptom. He had no other sign when admitted to St. Luke's Hospital, in March following. The spine was flexible and without deformity. A slight fulness was thought present in the soft parts of the right of the spines of the ninth and tenth dorsal vertebræ, where tenderness on pressure and some pain on motion were apparent.

Dr. Kinnicutt, under whose care he came, treated him by iodide of potash, quinine, blisters, and other remedies, though being unable to elicit any history of syphilis or tuberculosis, and quite soon diagnosed a tumor of the spine. Four weeks later the swelling of the soft parts had markedly increased, so as to make an induration of the parts two inches wide by three inches along the spine. Tactile sensibility now began to be disturbed in both legs, and then muscular power began to go. At the same time there was a line of hyperæsthesia around the abdomen which marked the limit between the anæsthesia of the legs and the normal abdominal skin. Two weeks later he could not stand without support. After this his power in

[1] This case was shown to the Surgical Society of New York, October 10, 1888, and mentioned in the New York Medical Journal, November 24, 1888.

the legs rapidly disappeared. He had annoying, uncontrollable twitchings of the legs, which were cyanotic when allowed to depend from the bed. The spine became rigid and very painful. The legs absolutely anæsthetic; abdomen tender and hyperæsthetic. A wasting hectic had set in. On May 10th he was growing rapidly weaker; had constant intercostal pain in the lower ribs, with girdle pains about the limiting line of disease. There was involuntary muscular twitching, with increasing incontinence of urine and fæces. By May 25th, affairs had gone from bad to worse, the man lay in an apathetic condition, suffering from the slightest motion of the spine, and with girdle and intercostal pains unabated. The presence of an active hectic led one to fear a serious general infection. A final consultation was held May 29th, at which Drs. Seguin, Weir, Peters, Kinnicutt, Bull, Ridlon, Murray, Shaffer, and myself were present. Previous explorations of the swelling had shown nothing, but to-day a drop of thick, shreddy pus was obtained, and on the following day I operated.

May 26th.—Under ether, an incision was made, six inches long, close to the spines, from the sixth to the twelfth dorsal. The laminæ being uncovered, some thick broken-down tissue and pus were scraped away. The laminæ were already bare of periosteum, and the spines and laminæ of the eighth, ninth, and tenth were cut away by rongeurs. This revealed a dense mass of tissue and desiccated pus occupying the entire calibre of the canal, and extending up and down in all two and a half inches. This compressed the cord tightly against the anterior wall. It was rapidly and thoroughly removed by a sharp Volckman spoon, until sound bleeding tissue was left on every side. The cord was not seen to pulsate. The cavity was packed with iodoform gauze—after bichloride irrigation—and an antiseptic dressing and plaster-of-Paris jacket applied.

On the eighth day, sensation began to return. In the fourth week he began to move his left leg and the toes of the right. His fever rapidly left. Pain disappeared, and appetite returned. In six weeks he moved both legs well. In ten weeks he went about in a rolling-chair. The third month, walked with crutches. At four and a half months, walked pushing a chair.

It is now eight months, and you see he walks well without support, is stout and hearty, and since the operation absolutely without fever, or evidence of tuberculosis. The tumor tissue was examined for bacilli, but nothing but cellular tumor elements and pus found.

The clinical evidence leads me to believe the neoplasm began between the theca and the posterior arch of the vertebræ, and then broke down, involving the bone. The bodies of the vertebræ are perfectly sound.

The second patient is one whose malady is more complicated, whose recovery is not yet so brilliant, but whose operation stands, as yet, quite unique. Intractable brachial neuralgia, nerve stretching, amputation, and finally, division of posterior roots of the sixth, seventh, and eighth cervical. Improvement.

Mr. I. R. T—— is forty-four years of age, an iceman. He was referred to me three months ago by Dr. C. L. Dana, of New York, to see if I were willing to undertake an operation, conceived by him, to relieve the patient of one of the most intractable of neuralgias of the right brachial plexus, appearing in the arm and forearm. The essential features of the operation were carried out as planned from the first by Dr. Dana. The patient's history is as follows:

Prior to this trouble, he had no disease—rheumatism, malaria, or specific. During the war a shell explosion left a small piece of it in his left shoulder, which was extracted on the field, and left only a small flesh scar; never otherwise injured. One year ago last May, he spent a day putting a zinc lining in a large butcher's refrigerator, and on the night following he first had a throbbing pain, localized in a single spot on the posterior surface of the right forearm, above the middle. The pain kept him from sleep. It was continuous at that site, but about one week later, there was added a paroxysmal pain giving a peculiar twitching sensation in the thumb, index, and middle finger of the same hand. He was treated by electricity, blisters, counter-irritants, and internal medication, by excellent doctors, but his arm grew steadily worse. The pain still localized over the forearm, and supplemented by the paroxysms of painful twisting sensation. There seems to have been distinct muscular spasm with the sensation of pain.

During the spring of last year there had ensued a disablement of the hand. The fingers were not readily closed nor extended. The hand was kept in a stiff position, the fingers semi-flexed. The forearm and hand were slightly emaciated. There was atrophy of muscle in the interosseous spaces. Dr. Dana and others thus saw him, and a diagnosis of ascending neuritis was arrived at. At this time he came under the care of Dr. W. T. Bull, at the New York Hospital. After a week the patient begged an operation, and the doctor stretched the posterior interosseous and ulnar nerves. The pain was not improved. If anything, it was worse.

On July 16th, at the patient's earnest request, the arm was amputated by Dr. Bull above the humeral insertion of the deltoid, and above any site of local pain heretofore complained of. The wound healed by first intention. As far as the eye could judge, all nerves in the arm were in a normal condition. When the wound had healed it was found there was no abatement of pain. It still had a "drawing" character, and he could feel the fingers twist just as if they were on. He left the hospital August 1st, if anything, complaining of more pain than before. He then came under the care of Dr. William Kemp, of New York, who again sought Dr. Dana's counsel. The patient had now got in the habit of taking morphine, one half grain every hour, to destroy the pain.

Of this interview Dr. Dana writes me thus:

"On September 25th I examined him again. The arm had been removed. The patient said he felt no better. There were twitchings and tonic contractions in the muscles of the stump. The patient had the Brauch-Romberg symptom, swayed in standing, and had a tendency to fall to the right when walking with eyes closed. Knee-jerks exaggerated and ankle clonus in right leg, all of which might be due to the morphine he was taking. There was much stiffness in the neck muscles. The patient could not rotate his head completely to the right, nor draw the head down to the right shoulder. The diagnosis, so far, had been neuritis—and of this there could be no doubt. The question was whether it might be due to a tumor or inflammatory process, either extra-spinal or extra-dural. An exploratory operation was advised with the idea, if no tumor was found, of cutting the posterior roots of the nerves transmitting pain. If it were a tumor, *that* could be removed. If it were ascending neuritis, cutting or resecting the nerve might stop it; while cutting the posterior roots would cause an ascending degeneration and destroy the sensory tract, even into the spinal cord."

At this juncture he went to Dr. Seguin for a month, and returning to Dr. Dana, was sent to me at St. Luke's Hospital. His condition then was as follows:

November 2d.—Had grown thin, was careworn and hollow under the eyes. Appetite fair, tongue coated. No fever. He gives evidence of sharp pain, every few minutes, in the stump of his right arm, and usually doubles over and grasps the stump with the other hand. When asked about it, says it jumps and the stump draws to his side when the pain shoots into the hands and fingers, as if they were still on, and he can feel them all drawn up. The pain seems to be genuine, and the recurrence every five or ten minutes. He says also that they keep up all night. Muscular atrophy is beginning to be marked about the shoulder, either from the disuse or degeneration. The deltoid, supra and infra spinati, and biceps are atrophied; while the lateral dorsi and pectoral major are short and thin, but still act strongly when called upon. A small, tender neuroma of the musculo-spiral nerve in the stump,

can be felt, and on pressure gives the same pain as is generally complained of.

November 7th.—Dissected out the neuroma under cocaine.

November 24th.—Not relieved by the removal of the neuroma. Urine 1.024, no albumen or sugar. Some oxalates.

December 31st.—Operated under ether, Dr. Bangs assisting, in the presence of a number of prominent neurologists and surgeons.

The usual surgical precautions were carried out. An incision was made along the ligamentum nuchæ on the right side, from the third cervical spine to the first dorsal. The soft tissues were quickly separated from the spine, and the right half of all the laminæ well out on the articular processes. With rongeurs the laminæ were quickly gnawed away from the spine to articular processes—thus bringing into view the rather full pulsating dural membrane of the cord.

The seventh, sixth, fifth, and half the fourth nerves were thus treated. Severe venous bleeding from under the latter was only controlled by an aneurism-needle protected by cotton and hooked up beneath the bone. Over two inches of dura was exposed. It was soft and allowed the finger pressure to feel the cord. No tumor was thus detected, nor did a director passed up and down the canal feel anything like tumor. There was no inflammation or disease of the hard parts. With a heavy curved hook I then explored the intervertebral foramina, and drew back the sixth nerve by hooking under it and pulling gently, so that a short loop of it was raised on my hook outside its point of exit from the dura, but inside the vertebral canal. Upon this root, thus raised, I applied a small metal electrode, while the opposite pole (a sponge electrode) was held on the back. Dr. Dana noted the effect. The same was tried on the seventh nerve, with less effect. My own observations, as did those of Prof. Markoe and others, coincided with Dr. Dana's. He writes: "On the day of operation, a faradic battery of one cell, moderate current, was used. A sponge electrode on the back, a metal point electrode on the nerve. When applied to the sixth nerve just external to the dura, it caused contraction of the supra and infra spinati, rhomboid, latissimus dorsi, pectoralis major, teres, and deltoid. The results of electrizing the seventh nerve were not so satisfactory, it not being certain that the point reached that nerve alone (on account of fluid that collected around the electrode). It was impossible to drag out the fifth nerve without exciting more hemorrhage from the venous sinus." The eighth nerve also was hidden below the bone, and it was thought enough had been done. The sixth and seventh were then again dragged up from their beds and cut square across just outside the dura. Both motor and sensory roots lie together at this point, so that they must have been severed. The wound was packed, entirely open, with iodoform gauze covered by a voluminous gauze dressing. He bore the operation well, but soon found his old pain seemed much the same—still low down in the hand.

January 2d.—Forty-eight hours after operation I felt that I ought to divide at least one more branch (the eighth), if I could do so, and if possible to examine the spinal cord, inasmuch as Horsley had not detected the tumor in his celebrated case until he had opened the dura. I therefore determined to do this, place the man prone, without ether, and open the dura, so as to get a clue to the sensations of the nerve-roots when handled. With the assistance again of Drs. Dana, W. T. Bull, and many others, I operated.

The patient was placed under a brilliant light, face downward, so as to maintain the operated part as the highest of the spinal axis. I carefully removed the packing, revealing a large, clean, dry wound, at the bottom of which lay the dura, throbbing and sound. Puncturing it with a knife, I slipped in a fine director and slowly let out the spinal fluid until it ceased to run. Then I slit up the dura for one and a half inch. The cord and membranes looked sound. The effect of evacuating two ounces of spinal fluid (carefully collected and measured) was practically nihil. The pulse did not change, and he experienced no sensations or pain. The dura was scarcely at all sensitive to cutting. I now picked up the roots of the eighth nerve within the dura at the level of the seventh nerve outside.

It looked normal, but I cut it close to the posterior spinal columns, and then snipped off a fourth-inch for microscopical examination. Handling this nerve-root gave him the greatest pain of anything I had done, and of a kind exactly corresponding with that which he constantly suffers. I had reason to hope, therefore, we had reached the offender. In addition I cut also the posterior roots of the seventh nerve close to the columns of the cord.

In two operations, therefore, I had cut the sixth nerve, both roots, outside. The seventh, both roots outside, and also the posterior root inside. The eighth posterior roots only inside the dura. It was observed that the contact of even a blunt soft instrument to the posterior columns gave a sharp agonizing pain over the entire body, the patient crying out, "Ah! I *can't stand* it."

We again tried the battery, and with regard to it Dr. Dana writes: "On the second trial, the patient being conscious, stimulation in the same way—of the peripheric end of the cut sixth nerve—caused contraction of the supra and infra spinati and rhomboid. Of the seventh nerve, contraction of the pectoral, latissimus dorsi, and adductors of the arm, with pains such as he usually suffers. Of the eighth nerve, similar contraction and intense 'drawing pain,' exactly such as is usually felt."

The slit in the dura was now sutured with fine catgut. A little cocaine had been injected along the cut wound half an hour before, and this allowed of painlessly suturing the entire length of the wound. Immediate union was thus obtained by second intention, and leaves a small linear scar. The patient had more or less of pain in the arm in the next ten days, but it changed in character. It no longer went down into the fingers. It was a "drawing of the stump," as he expressed it. It ceased to go up on the shoulder as it once did. He was allowed enough morphine to quiet pain for eleven days, when I deemed it best to let him sit up and stopped the drug entirely.

He missed it, but quickly got used to it, and since has had even less pain than when he was getting his morphine to quiet it. He walked freely at the end of the third week, and soon went in the open air. His gait is now as steady as for months past, and he can walk a crack in the ward any distance.

His temperature was 101° F. on the second day, and 102° F. on the fourth, but declined from that to normal on the tenth. The appearance of the upper arm and stump is one of increasing atrophy. There is no voluntary movement of the supra- or infra-spinatus, deltoid, or biceps, but there is of the latissimus and pectoral, though both are shrunken from disuse. There is anæsthesia of the skin of the entire outer side of the arm from the deltoid region downward, extending across the shoulder from the centre of the clavicle to the centre of the scapula. This area of the skin showed a short period of irritability, without sensation, from the fourth to the eighth day after the root section, as shown by getting quickly and persistently suffused when brushed over or handled; but when pinched retaining an extreme blanching at that point which did not recover for two or three minutes. This entire area is now, however, normal in appearance.

In considering the lessons drawn from these cases it is to be remembered that in any path of study knowledge never comes entire at once, but piecemeal. Truth presents herself in fragmentary form, and we put the pieces together; so that, while I do not present the case of cervical operation as a brilliant result as yet, so far as completely relieving the pain goes, I offer it as a unique case making a quick recovery from an operation, as conceived by Dr. Dana, at once simple and scientific.

The other case of spinal pressure from a degenerating tumor successfully operated on, and restoring the man to health, is the only one I find on record in this country, though others have been recorded abroad—MacEwen, of Glasgow, claiming to be the first to accomplish this result, five years ago. Since that time he has operated on five cases, two of whom died of tuberculosis.

Most cases of pressure-myelitis have no striking hectic fever. Yet two of MacEwen's cases had at the time he operated, and these two died. He, therefore, draws the conclusion that no case is "fit for operation in which the temperature does not run an even, regular, and continuously afebrile course." He shows thereby a suspicion that the pressure-myelitis paraplegia, plus the hectic, indicates a diffusion of tuberculosis. The case you have seen, therefore, stands of itself as an argument to refute this error, for the removal of the one focus of trouble entirely dispelled the hectic.

MacEwen's cases show, happily, that improvement does not cease at six months. His patients, just able to get along without crutches at six months, can walk many miles two or three years later.

With regard to the case of neuralgia of the arm, no indisputable diagnosis had been made prior to my operation.

The man had neuralgia, but the cause of it, even such eminent neurologists as Drs. Dana, Seguin, Amidon, Starr, and others, were not united on.

It was believed to be ascending neuritis, but might be spinal tumor, or a delusional pain (Seguin) aggravated by morphine.

The language of pain is not at all times plain. If it were an ascending neuritis, could we expect to relieve it either by nerve-stretching, amputation, or neurectomy?

It has always been acknowledged difficult to get ahead of a neuritis of this type. The late Dr. Sands operated once on a similar case to this man's, by excision of the brachial plexus all the roots in the neck, but found it very hazardous and unavailing. It also left the arm powerless. It seems to me reasonable that the posterior roots should be severed alone, as they alone transmit sensation to the cerebrum.

The operation has endorsement from neurectomies of the sensory fifth nerve for the cure of tic douloureux.

There remains one point for consideration which this case of section of the sixth and seventh nerve will help to elucidate.

The exact supply of the nerve-roots to the muscles of the arm has been somewhat a matter of conjecture, and frequently subject to revision.

William Thorburn, of Manchester, has only very recently published the results of study of many cases of fractured cervical spines, in which nerve-roots were injured with varying paralyses. The conclusions from this attractive and well-observed series of cases seem to leave some gaps in testimony, and errors which further study will correct. My case gives some points of value.

Thorburn places the pectoralis major and latissimus dorsi muscles in the supply of the sixth root. Yet in my case these are not paralyzed, though I have cut the sixth and seventh. Therefore these must be largely innervated from the fifth.

That there was no error in identifying the sixth, is shown by the supra- and infra-spinati supply and the anæsthetic area.

STATISTICS OF CREMATION IN EUROPE.—*The Flame*, the organ of the Cremation Society of Berlin, gives the following as the number of cremations which have occurred in Europe up to August, 1888: In Italy, 998; Gotha, 554; Sweden, 39; England, 16; France, 7; Denmark, 1. The number reported in America during the same period is 287. The following is the total membership of cremation societies in the countries mentioned: Sweden, 3,012; Denmark, 1,326; Holland, 1,128; Germany, 612; Italy, 580; Hamburg, 438; Switzerland, 390.

Progress of Medical Science.

EXANTHEM DUE TO SULFONAL.—Dr. Engelmann has observed an eruption following the use of thirty grains of sulfonal in a patient having insomnia. The sleeplessness was due to recurrent attacks of dysmenorrhœa. The woman took the sulfonal at seven in the evening, without hypnotic effect however. The following morning a bright scarlet exanthem appeared on the chest. There was moderate itching, but no other symptom of disease. The rash spread over the arms and abdomen, and then after two days disappeared, the itching meanwhile having become more troublesome. The writer attributes the appearance of this drug-eruption to vaso-motor disturbance (*Münchener Medicinische Wochenschrift*).

EXTRA-GENITAL SYPHILITIC INFECTIONS.—Dr. O. Petersen has collected all the available statistics showing the relative frequency of extra-genital chancre. In Mauriac's Handbook, 1,773 cases of syphilis in men are collated from various authors, in which were only 76 cases (4.3 per cent.) of indurated chancre; these were situated as follows: Lips, 36; anus, 12; abdomen, 9; tongue, 8; toes, 3; fingers, 2; eyelids, 2; gums, cheek, ala nasi, and buttocks, each 1. In Dr. Petersen's venereal service at the Alexander Hospital, during the seven years from 1878 to 1884, there were 1,208 cases of syphilis in men. Among these there were 23 cases (1.9 per cent.) of extra-genital chancre, distributed as follows: Lips, 11; anus, 9; abdomen, 2; cheek, 1. Professor A. S. Gray, of Kazam, puts the percentage of extra-genital chancres at 8.9, but he does not give the number of cases from which this percentage is reckoned. Bogolyuboff, in his report of the Kronstadt Marine Hospital, gives 4 cases of extra-genital chancre (lips, 2; eyelids and tonsil, each 1) in 753 cases of syphilis, or one-half per cent. Grödinger reports of 231 cases of syphilis in the Riga Hospital, 3 of extra-genital chancre (lips, 2; fingers, 1), or 1.3 per cent. In the case of women the figures are somewhat different. Mauriac has collected the statistics of 291 cases in which the seat of the chancre was given, and finds it on other parts than the genitals in 19 cases (6.5 per cent.), distributed as folfows: Lips, 9; anus, 5; nipples, 2; tonsils, buttocks, and gums, each 1. Kobylin reports 6 cases of hard chancre of the nipples in 77 cases of syphilis in women presented for treatment in the Kalinkin Hospital during the year 1880, and Sperk states that extra-genital infection occurs in 24.3 per cent. of the cases of syphilis in women, occurring in the same hospital. Plinatus met with 13 cases of syphilis contracted by women who nursed the infants in the Foundling Asylum of the Kreuzeserhöhung Sisterhood during the years 1870–73. Of indurated chancres of the tonsils, Dr. Petersen has collected the reports of 42 cases. In 30 cases the particular tonsil is mentioned, and of these the chancre was situated on the right tonsil in 18 cases, and on the left in 12. It occurred rather more frequently in men than in women, and usually in children from three to fourteen years of age, though one case was reported in a woman aged fifty-four years. To these statistics the author adds a case of his own, the only one seen by him during a venereal practice extending over more than ten years. The patient was a merchant thirty-five years of age, and the chancre was situated on the right tonsil. His wife, who was pregnant, had a chancre on the gums. She gave birth to a child who soon presented syphilitic symptoms, and a few months later the wet-nurse of the infant acquired a hard chancre of the left nipple. —*Journal of Cutaneous and Genito-Urinary Diseases*, January, 1889.

A NEW WAY OF DIAGNOSTICATING SHOULDER PRESENTATION.—Quiz Master—How do you diagnosticate a shoulder presentation? Student—By feeling for the hair in the axilla.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 9, 1889.

VAGINAL LIGATURE OF THE UTERUS FOR DISPLACEMENTS.

THE routine treatment of uterine displacements by pessaries or tampons appears to be falling into disfavor with many enlightened practitioners and specialists. New methods of therapy, mostly of a surgical kind, are being prominently brought to the notice of the profession. We have the Alexander Adams operation and we have hysterorrhaphy, both decided innovations in the range of hitherto approved methods. The most recent operative measure intended to effect a cure in many cases of intractable malposition, including total prolapus uteri, is advanced by Dr. O. Schücking, of Pyrmont. This surgeon boldly proposes to pass a ligature through the substance of the uterus, and thus to restore the organ to its normal position. He gave a detailed history of a series of successful cases before the recent meeting of German Naturalists and Physicians. The Berlin correspondent of the *Medical Press* gives the following account of Schücking's method of procedure: "After thorough disinfection of the vagina and endometrium the patient is placed in the lithotomy position, the upper part of the body being placed low (hips raised). After emptying the bladder and the introduction of a Sims' speculum the anterior lip of the cervix is seized with a Museux forceps, and the fundus uteri is brought forward by means of a uterine sound. For the purpose of passing the needle he uses a specially constructed instrument. The needle is then passed to the fundus uteri, and the uterus is drawn strongly down by the right hand, that holds both the forceps and needleholder, in such a way that the os points to the left and the fundus to the right side. By gentle side-to-side movements he then tries to find the point of the uterus, on which the instrument within is pressing, an assistant at the same time drawing the bladder to the left. The needle is then passed through into the vagina. The operation is not difficult of performance in the case of women who have borne children, and in whom the pubic arch is rather flat, but where the uterus is enlarged, as it often is, and the parts are narrow or rigid, it may not be at all easy. The ligature is then seized with a curved hook, drawn a little forward, and cut off from the needle. The two ends are then tied. At the close an iodoform bougie is placed in the vagina and bladder. Ice is placed on the abdomen for twenty-four hours, and the thighs are flexed in order to reduce the tension on the suture. Until the suture is removed an iodoform bougie is placed in the vagina every second or third day. Some bladder troubles were remarked after the operation in nearly all the cases of retroflexion; but, on the other hand, bladder troubles present beforehand in cases of procidentia ceased after the operation. The sutures were removed in from six days to three weeks, once in six days, in eleven cases of retroflexion from the ninth to the fourteenth day." The discussion which followed the reading of Schücking's paper is published in the *Allgemeine Medicinische Central Zeitung*, October 31, 1888. Most of the speakers were inclined to be rather sceptical, especially in regard to the permanency of the good results reported to have been secured by vaginal ligature of the uterus. In the views of the sceptics we must for the present concur, and we would further advise all those who may desire to become imitators of the German gynecologist to practise his method on the cadaver before subjecting the living female to an experiment not devoid of danger.

THE NEXT PHARMACOPŒIA.

BEFORE long, the body of men representing our colleges of medicine and pharmacy, the profession at large, and the government medical services will begin to lay plans for the next revision of the Pharmacopœia. It is not an exaggeration to say that, in some respects, the next meeting will be more important than any which have preceded. A primary reason for this is that no previous ten years have been so rich in pharmaceutical discoveries as has the last decade. In spite of the crowded list of officinal remedies in the Pharmacopœia of 1880, many new aspirants for therapeutic honors have appeared, and have come to stay. Antipyrine, antifebrin, salol, cascara, sulfonol, and hosts of others cannot now well be dispensed with.

A second reason is that, of late years, an effort more systematic than ever before has been made to simplify therapeutics, and reduce them to rational principles. We hold that physiological and toxicological action is the basis on which any systematic therapeutics must be based. From this starting-point we can work intelligently. Even here, our conclusions, empirically drawn, are not always the ones suggested by the premises. The ever-varying factor of the human organism shows well, here, how medicine can never be in some respects an exact science. To further the progress in the direction indicated, is partially the province of the Pharmacopœia.

This book is much neglected by both the student and the practitioner. It is never suggested to the former as a needful acquisition. It becomes entirely disassociated from his study of materia medica. Naturally, it is rarely referred to in his post-student days. We doubt if the libraries of a hundred physicians taken at random would show more than a dozen copies, and probably some of these would be regarded by their owners as "standard" works, which have been defined as "books which everybody owns and nobody reads."

We think certain features of the Pharmacopœia might be much improved in the next edition. We must, however, remember that the book is for the whole country. Remedies quite popular in one section are rarely used in

another. This fact will limit our criticism somewhat. If the Pharmacopœia is made simpler and more attractive, the student will use it more. Useless drugs should be removed. Certain classes of preparations might be dispensed with. The "abstracts" have proven a useless addition. No one wants them now in these days, when the skill of the manufacturing chemist has been carried to such a nicety. The forty odd preparations of iron could be reduced to half that number. The same might be said of rhubarb, aloes, and many others.

We speak earnestly on this topic, because of our conviction that no branch of medicine is so unsatisfactorily taught as that portion of materia medica which treats purely of remedies. This unsuccessful teaching results, not from a lack of able men, but from the pursuance of wrong methods. The more extended a man's clinical experience, the narrower becomes, as a rule, his circle of remedies, and the greater his skill in the use of those retained. Now, if we could anticipate this by teaching students the effects and uses of say fifty of the leading remedies, we should amply equip him for a professional start, and give him much clearer conceptions of materia medica than he has at present.

THE NAVAL MEDICAL SERVICE.

THE Naval Medical Examining Board, now in session in Philadelphia, will hold its sessions at the Naval Hospital, Brooklyn, N. Y., beginning April 1, 1889. There are fourteen vacancies in the grade of assistant surgeon, and it is hoped that sufficient candidates will come up to fill all the places. Any young man in good health and without physical disabilities, who is capable of passing a good graduating examination before a medical college faculty ought to be successful before the Naval Board. The service gives a man at once a good income, and it has attractions which ought to make the task of filling the vacancies an easy one.

A NEW INFECTIOUS DISEASE.

DR. GUIDO BORDONI UFFREDUZZI has described (*Zeitsch. für Hygiene*, Bd. III.) a new infectious disease which affects man and some of the lower animals. It runs an acute fatal course, and resembles a form of septicæmia. Uffreduzzi thinks it identical perhaps with the disease known as "Hadernkrankheit." Two cases only have been observed. At the autopsies there was found in one case a hemorrhagic infiltration of the bronchial mucous membrane, and of the bronchial and mesenteric glands; in the other case there was a very intense hemorrhagic intestinal catarrh. Bacilli were found in the blood and organs. These were carefully cultivated in the bacteriological laboratory at Turin, and the differential characters established. The organism, to which the name *proteus hominis capsulatus* is given, was inoculated in lower animals, and its pathogenic powers established. The distinctive character of the new disease is thus based upon bacteriological grounds. Symptomatically it appears to resemble a severe type of septicæmia or malignant carbuncle. We can only trust that the *proteus hominis capsulatus* is "a scanty sort of water-beast" that does not wander beyond the limits of Turin.

News of the Week.

PITTSBURG DOCTORS MUST WAKE UP.—"There are no human beings on the face of the earth to-day that have less real knowledge of their own business than the doctors. Beyond a few well-known diseases which anyone can master, they are not a whit wiser than anybody else. That the doctors will have to wake up is quite plain to see. People read so much nowadays that some have even more information on the newest things in medicine than the doctors themselves."—*Pittsburg Leader*, December 9th.

DAMAGES FOR FRACTURE OF THE RADIUS.—An interesting, though not unusual, case has just been tried in Boston, in which a physician was sued for $10,000 for failure to treat correctly an injury involving a fracture of the radius near the wrist-joint. The jury, after being out for twenty hours, found a nominal verdict for the plaintiff in the sum of ten dollars without costs.—*Boston Medical and Surgical Journal.*

PROTECTION FOR AMERICAN PHYSICIANS.—In an editorial upon this point, it was stated that it was not just to American physicians that men who did not know enough to get a license to practise in Germany should be allowed to come over here, set up as qualified practitioners, and practise for twenty-five and fifty cents a visit, for Americans, even if they have a degree of M.D., cannot practise in Germany on the same conditions. This does not affect the humor of the following free-trade anecdote, but it shows how the mind distorts all social problems when it is in the grip of a special economic dogma. With this antidotal homily we append the following, from the *Philadelphia Record:* "More Protection Wanted. (The effect of an editorial in a contemporary.)—Workingman—'See here, I want protection.' Great Statesman—'Certainly, certainly; you shall have it. What's the matter?' 'Well, sir, some of these 'ere foreign doctors know so much that they keep folks alive too long. I want foreign doctors kept out o' this country. I'm a grave-digger.'"

NEW YORK COUNTY MEDICAL ASSOCIATION.—At the Annual Election, recently held, the following officers were elected: *President*, Charles S. Wood; *Vice-President*, George T. Harrison; *Recording Secretary*, P. Brynberg Porter; *Corresponding Secretary*, Augustus D. Ruggles; *Treasurer*, John H. Hinton; *Member of the Executive Committee*, S. B. Wylie McLeod. The annual reports showed a healthy financial condition, and an encouraging increase in membership.

THE JOURNAL OF THE RESPIRATORY ORGANS is the title of a new medical monthly, edited by Dr. J. Mount Bleyer, and published in this city.

PASTEUR WANTS MONEY.—It seems that M. Pasteur rather expects that nations which send patients to his institute for treatment should contribute to its support. England almost alone of European nations has failed to contribute any money. America has, so far as we know, contributed nothing. Neither have we any antirabic institutes (though Chicago is credited with one), so that persons bitten by mad dogs naturally go to Paris if they believe in

Pasteur's methods. There are now about twenty antirabic institutes scattered over the world.

Dr. H. D. Bruns has been made Pathologist to the New Orleans Charity Hospital, as successor to the late Dr. H. D. Schmidt.

Lay Prescribing of New Remedies.—The self-prescriber has already heard of sulphonal, and is taking it in the maximum dose in order to produce sleep. He is also recommending it to his friends who cannot sleep, in doses which are not free from danger. The popular use of antipyrin, which has been going on for over a year, has done no little injury; we have known thirty grains to be advised by one layman to another as an initial dose. We predict that the time must come, through the multiplication of these potent neurotic medicines, when physicians will insist upon the non-renewal of these potent prescriptions by pharmacists without a written order. It seems to us quite probable that we have simply arrived at the threshold of this department of chemical work, and that the profession will be compelled to throw additional safeguards around the unauthorized use of these powerful agents.—*Medical News.*

Awarding the Prizes of the Académie des Sciences.—The Paris correspondent of the *British Medical Journal* gives an account of the awarding of prizes by the Académie des Sciences. In Medicine and Surgery, Dr. Hardy received the Prix Monthyon for a new treatment of itch by baths and lubrications, which he has practised since 1852 at the Hôpital St. Louis (!). Dr. Hénocque received a Prix Monthyon for a new method of spectral analysis of the blood in hospital practice. A third Prix Monthyon was awarded to MM. Follin and Duplay for their treatise on Surgical Pathology. The Prix Bréant was given to Dr. Hauser for a work on the Spread and Prevention of Cholera. The Prix Barbier was divided between Dr. Ehrmann, of Mulhouse, who has published some interesting studies on Artificial Palates, and MM. Raphael Dubois and Leroy for a new ophthalmometer. Dr. Hache received the Prix Godard for his work on the Physiology and Pathology of the Bladder. The Prix L'Allemand was divided between M. François-Franck and M. Blocq. M. François-Franck has published a work on the Motor Functions of the Brain and Cerebral Epilepsy, being an account of his work for the last ten years. M. Blocq has made some interesting researches on Spasmodic Muscular Contraction. The Prix Monthyon in Physiology was divided between Dr. Augustus Waller, of St. Mary's Hospital, London, and M. Léon Frédericq, Professor at the University of Liège. The work which Dr. Waller presented to the Académie, was on "The Electro-motor Properties of the Human Heart." Dr. Waller's discovery is remarkable in being the only undoubted instance of an electrical change caused by a natural physiological action on man; it is a definite connection between the exact laws of physics and the less precise laws of physiology.

An Illustration of the True Value of Patent Medicines.—The effects of the "Scotch Oats Essence" Company, in New York, were sold out recently by the sheriff. Sixty-three gross of "Scotch Oats Essence" realised about four cents a bottle, the retail price being one dollar a bottle.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-third Annual Meeting, held in the City Hall, Albany, February 5, 6, and 7, 1889.

First Day, Tuesday, February 5th—Morning Session.

The President, Dr. Samuel B. Ward, called the meeting to order at 9.50.

The meeting was opened by prayer by Rev. Dr. James Ecob.

PRESIDENT'S INAUGURAL ADDRESS.

After thanking the Society for the honor conferred upon him in electing him President, he stated that the most important event to the profession in this country the past year had been the meeting of the Congress of American Physicians in September last.

Attention was called to a decision by Judge Learned, of the Supreme Court, who virtually decided that no man could be adjudged insane and sent to an asylum on the certificate of two physicians, in the way usually followed, unless he had shown that he was dangerous to himself or others. The physician who pronounced one insane who had not shown himself dangerous would, according to this decision, be liable to suit for damages.

Attention was called to the question of the propriety of dividing the meetings into two sections, medical and surgical.

On motion of Dr. Potter, of Buffalo, the suggestions contained in the inaugural address were referred to a committee of three.

The President appointed Dr. Potter Chairman of the committee; Dr. George Seymour, of Utica; and Dr. W. G. Tucker, of Albany.

The President appointed the following Committees:

Business Committee: Dr. D. B. St. John Roosa, Chairman; Dr. Ely, of Rochester; and Dr. Ford, of Utica.

Committee on Registration: Dr. William F. Brown, of Steuben; Dr. W. L. Pearson, of Schenectady; and Dr. C. M. Culver, of Albany.

The names of those applying for permanent membership was referred to the Nominating Committee.

The Committee on Prize Essay reported that no essay had been offered in competition.

Dr. B. F. Sherman offered the following:

Whereas, There is now a bill before the Legislature which requires those commencing suits for libel against publishers and editors to give bail for all costs; and

Whereas, Ninety per cent. of all suits brought for malpractice are for blackmail; therefore,

Resolved, That the Committee on Legislation be hereby instructed to use all honorable means to have this bill amended so as to include cases of malpractice.

The motion was carried.

REPRESENTATION FROM INCORPORATED SOCIETIES.

The President was empowered to appoint a committee of three to report on what shall be the basis of representation from incorporated medical societies in the State. He appointed Drs. Wey, Sherman, and H. P. Loomis.

REPORT OF COMMITTEE ON LEGISLATION.

Dr. Alexander Hadden, Chairman of the committee, read the report. The committee had exerted its efforts in favor of the legislation regarding the pauper insane which had been approved by the Society at the last annual meeting.

It approved of the principle of exempting from duty imported articles used in the healing of the sick, but had not petitioned Congress in the form suggested by the Georgia State Medical Society, as some want of agreement existed regarding the form.

The committee had also exerted its efforts in behalf of legislation restricting undertakers in the use of embalming fluids. An association of undertakers and others had prevented the desired legislation. Undertakers should be restricted from using any material in the embalming process which would complicate medico-legal investigation without special permit.

STATE BOARD OF MEDICAL EXAMINERS.

The committee proposed to urge the passage of the bill introduced into the Senate, January 28th, being essentially the compromise bill creating a State Board of Medical Examiners, which had first been brought up some years ago. Consideration of this report was postponed until 4 P.M.

DR. E. V. STODDARD read the report of the Special Committee on Revision of the Pharmacopœia. A congress for revising the Pharmacopœia will be held in 1890.

DR. CHARLES STORER, of Amsterdam, read a paper on

THE MUNICIPAL CONTROL OF DIPHTHERIA.

Even though the existence of a specific microbe had not been established, yet the sanitarian must treat diphtheria as a specific infectious and contagious disease. The plan of municipal control, carried out to some extent in Amsterdam, had been to send postals to physicians to return, announcing, every case at its commencement. The parents received instruction of the general nature of the affection, how to disinfect clothes, necessity for isolation, etc. The municipality should provide pure water, see that cellars were impervious to water, and thus prevent infection of ground air, etc. The school was the greatest centre of the contagion.

DR. J. LEONARD CORNING, of New York, read a paper entitled,

THE INFLUENCE OF THE MIND UPON THE BODY.

The author sought to give the truths and delusions of psycho-therapeutics, especially of mind-cure and faith-cure. By the ordinary operations of the mind sensation might be evoked, diminished, exalted, or perverted; only undivided attention to a particular part of the body was needed. Expectation or suggestion acted still more forcibly in the same way. Such effects were largely evanescent, and were functional or nervous in their nature. They were impotent to affect established histological changes. The mind-healer was the anarchist of science, and represented a Quixotic and often mischievous exaggeration of a single principle of legitimate medicine, and one which could be applied in only an exceedingly limited number of cases.

THE PREVENTION AND TREATMENT OF TYPHOID FEVER.

DR. STEPHEN S. BURT, of New York, opened his paper with a statement of statistics of large mortality from typhoid fever in New York and Providence during two months. The most common means of spreading enteric fever was drinking-water. Boiling would render infected water harmless. More attention should be given to drainage and general cleanliness compared with that given to decoration. He was in accord with those who believed pyrexia was a conservative process. The neurotic hypothesis of the pyrexia seemed to have been established. Was not too much attention given it relative to importance of other factors? Absolute recumbent position was recommended, fresh air without draughts, no medicine which disturbed the stomach, milk-diet, alcohol according to indications, opium in intestinal hemorrhage. Cold water was liable to produce shock; tepid water preferred.

DR. EUGENE BEACH continued the discussion with a paper on

DISEASES OF THE CIRCULATORY ORGANS COMPLICATING OR FOLLOWING TYPHOID FEVER,

in which he cited four instances of thrombosis, with more or less phlebitis, in his own practice, and a number of others in literature, although such complications were, rare. It might consist of embolism, phlebitis, carditis pulmonary infarctions.

DR. SIMON BARUCH, of New York, read a brief paper, discussing the

HYDROPATHIC TREATMENT OF TYPHOID FEVER.

The only advantage from antipyretic medication, seemed to be that it enabled the patient to die with a normal temperature. He considered the reduction of the temperature, which the cold-water treatment effected, to be of only secondary importance; the chief benefit was due to its influence upon the nervous system, invigorating the pulse, improving appetite and digestion, obviating complications, and carrying the patient over dangerous points. The cold-water treatment had reduced the mortality of typhoid fever from 21 per cent. to 1.7 per cent.

DR. BRUCE, of New York, had known some cases of sudden death from cold bath in typhoid; sponging with tepid water was less dangerous, and gave better results. He added a fair proportion of alcohol, and followed the sponging with smearing the body with sweet oil.

DR. GOFFE had had two cases of phlebitis in typhoid fever, in one of which he was giving sixty grains of quinine and also large quantities of whiskey. He suggested that the quinine might have been the cause of the phlebitis.

DR. B. F. SHERMAN had seen two cases of phlebitis in typhoid, in neither of which quinine could have been the cause.

DR. BELL, of Brooklyn, thought the benefit from water was largely due to reduction of temperature.

DR. THOMAS E. SATTERTHWAITE, of New York, then read a part of a paper entitled,

EMBOLIC PNEUMONIA, BASED UPON A RECORD OF EIGHTEEN FATAL CASES.

Embolic pneumonia might take place in the course of typhoid fever, from pressure of tumors, as cancer, on vessels, from cardiac thrombi, white, mixed, or red, and other conditions. It was chiefly when the embolus lodged in terminal vessels that it did serious harm. Pulmonary infarction was not easily produced in normal lung, and even in the crippled lung; if the respiratory movement were free it was not likely to occur from embolism. The pathological appearances of embolic pneumonia were described.

DR. L. E. HOLT, of New York, read a paper entitled,

PREVENTION OF SUMMER DIARRHŒA IN INFANTS, VIEWED IN THE LIGHT OF THE LESIONS.

The author was led, from post-mortem studies, to the belief that dyspeptic catarrh of infants often went on to production of follicular ulcers; these were frequently present, although the child increased in weight, and the mother overlooked the dyspeptic and diarrhœal symptoms; that such follicular ulcers usually precede what was termed summer diarrhœa. He had never found evidence of follicular ulcers having healed at the autopsy, and the inference was that most of the cases were fatal.

Careful attention should be given all cases of intestinal catarrh, and a cure be effected as soon as possible. Attention to food and digestion was very important. Some studies of the capacity of the stomach of infants led him to the opinion that hand-fed infants were very commonly over-fed.

DR. G. M. HAMMOND read a paper entitled,

THE TREATMENT OF CHRONIC CONSTIPATION BY ELECTRICITY.

Text-books made little mention of the treatment. He read the histories of a few of forty-one cases of chronic constipation treated by galvanic electricity. A better result was obtained by introducing the negative electrode into the rectum than when applied over the abdomen. The faradic current had been of service only in giving tone to abdominal muscles, for which it was used in one case. His

results had been most successful, particularly in cases where patients had movements previously only from large doses of cathartics.

Dr. O. F. Currier, and Dr. Burt, of New York, and Dr. H. R. Hopkins, of Buffalo, confirmed the statement of the author regarding the value of this treatment. The galvanic current also excited other hollow viscera to action, as the atonic bladder.

Dr. Holt had found galvanism successful in obstinate cases of nocturnal emissions, but Dr. Baruch said his experience had been unfavorable.

Afternoon Session.

REPORT OF COMMITTEE ON HYGIENE.

Dr. E. V. Stoddard read the report. The Committee had investigated the question this year of how to make local health boards more effectual, and had found certain facts to recommend a change in the so-called territorial unit of organization. Under the present law this is the village, town, or city; it was a question which they proposed to study, whether it might not better be the county. The health officer (who preferably should not be a physician) should have his office at the county seat.

The Committee suggested the passage of the following resolution:

Resolved, That the detention of the acute insane in county asylums, as shown by the Report of the State Board of Charities, is an evil which should not be tolerated in any case, whether pauper, indigent, or private patient; that it should be forthwith abated; that the recommendation of the said State Board of Charities for regulation and restriction of county care should be acted upon immediately.

Dr. A. Jacobi moved to amend, and include chronic as well as acute insane, placing both under State, instead of county, control. The amendment, after some debate, carried.

Dr. James B. Hunter, of New York, then read a paper (see p. 147) entitled,

THE TECHNIQUE OF VAGINAL HYSTERECTOMY.

Dr. T. A. Emmett, of New York, said the question of choosing vaginal hysterectomy in preference to high amputation would have to be determined by the relative prolongation of life. He thought the operation recently done by Dr. L. A. Stimson was destined to become the choice operation in such cases, viz., to secure the uterine vessels from above after laparotomy, and remove the uterus from below.

After remarks by Dr. Currier and Dr. Potter, Dr. Hunter closed the discussion, and said he thought the procedure adopted by Dr. Stimson was suitable rather to cases of uterine tumors, not to cancer.

PURULENT CONJUNCTIVITIS OF INFANTS, AND BLINDNESS IN THE STATE OF NEW YORK.

Dr. Lucian Howe, of Buffalo, read this paper, which included the report of the Committee on Blindness. He called attention to the fact, demonstrated on charts, that there was a very rapid increase of blindness in this country; that it was due to the purulent ophthalmia of infants; that by the use of methods already known (Credé's in particular) the percentage of blindness could be very materially lessened; that no systematic effort to do this was being made in this country either among physicians or others. Credé's method consisted simply in thoroughly cleansing the eyes of every newly-born infant, and dropping in a two per cent. solution of nitrate of silver.

The Committee on Legislation was instructed to recommend to the Legislature passage of a law requiring midwives and others to report all cases of ophthalmia as soon as they became informed of its existence.

The question of presenting a bill for the creation of a

STATE BOARD OF MEDICAL EXAMINERS

was then taken up, and after criticisms of the old bill presented to the Legislature in 1886, and again recently introduced at the suggestion of the Committee on Legislation, under the mistaken impression that the Society had so instructed it to do, a resolution to the following effect was passed:

Resolved, That this Society accept a suitable bill which gives it a majority representation on a State Board of Medical Examiners, and one which does not interfere with the laws of the State regulating the practice of medicine as codified the past winter.

Dr. Andrew F. Currier, of New York, then read a paper entitled,

THE DISORDERS OF MENSTRUATION,

which he divided into those of amenorrhœa, dysmenorrhœa, oligomenorrhœa, polymenorrhœa, and adipomenorrhœa. It was a peculiarity of the organs of the body, that when their functions were performed normally they were painless. This rule might find an exception in labor, but not in menstruation.

In the discussion, speaking of vicarious menstruation, he recommended electricity to re-establish circulation in the pelvic organs, when the hemorrhage from the nose, or elsewhere, would give way to menstruation.

Dr. Jacobi thought vicarious menstruation, and nosebleed in young people, was frequently due to insufficient development of the circulatory apparatus, particularly the heart, and tonics and cardiac stimulants were indicated.

Dr. Wey, of the special committee, reported in favor of admitting one delegate from voluntary incorporated medical societies.

The Committee on By-Laws was instructed to embody this suggestion in a by-law, to be acted upon.

THE MEDICAL VIEW OF INEBRIETY.

Dr. Crothers, delegate from the Connecticut State Medical Society, showed that inebriety had been regarded at certain places, at different times, as a disease, and at the present several societies, and journals, and many institutions were founded on this view; yet the general profession had given the subject little attention. Each physician should examine cases of inebriety for himself, and treat the patients as though afflicted with a disease. The various conditions preceding and following birth, tending to develop the inebriate (not necessarily alcoholic) habit, were reviewed.

Evening Session.

Dr. H. G. Piffard, of New York, made remarks on

OFFICE PHOTOGRAPHY WITH THE FLASH LIGHT,

and exhibited a number of stereopticon views of skin affections. The light was from magnesium ignited by an alcohol flame. The apparatus was easily portable.

CRANIAL MEASUREMENTS IN TWENTY CASES OF INFANTILE CEREBRAL HEMIPLEGIA,

was the title of a paper by Drs. E. D. Fisher and Frederick Peterson, of New York. Dr. Fisher, owing to limited time, gave a summary of the paper, stating that the measurements in the twenty cases had been made by Dr. Peterson, and consisted of twelve different measurements in each instance, such as could be made by any physician in his office. The measurements and volume in every case of the twenty were below normal, and on the side opposite the hemiplegia the skull was reduced to a considerable extent. The patients had become adults, but the lesion was congenital or infantile. Infantile hemiplegia would seem to be due often to delayed labor, but not, as some had claimed, to use of the forceps.

In treatment, Dr. Fisher suggested mental training with muscular exercise.

Dr. Ford cited a case in which good results had followed persistent treatment of the kind suggested by the authors, and Dr. A. Jacobi stated that changes in the form of the brain after infancy, or ossification of the sutures, would not manifest themselves in the skull, and Dr. Fisher coincided in this statement.

Dr. Jacobi further impressed the danger of hemorrhage in asphyxia of the newly-born not quickly resuscitated.

Dr. William Hailes, of Albany, then read a paper giving the history of an unusual case of intubation of the larynx for croup.

After adjournment, the members attended a reception by the President, at his residence.

The following is the Nominating Committee: First district, Dr. George H. Fox, of New York; Second district, Dr. Burke Pillsbury, of Middletown; Third district, Dr. Herman Bendell, of Albany; Fourth district, Dr. James Macfie, of Fort Covington; Fifth district. Dr. H. G. Du Bois, of Camden; Sixth district, Dr. Henry Flood, of Elmira; Seventh district, Dr. J. P. Creveling, of Auburn; Eighth district, Dr. L. A. Weigel, of Buffalo; delegate at large, Dr. W. W. Potter, of Buffalo.

Second Day, Wednesday, February 6th—Morning Session.

RESTRICTING ENDORSEMENT OF DIPLOMAS.

Dr. Dean, of Jefferson County, read a resolution adopted by his county society, suggesting legislation restricting the power of medical colleges, in this State, endorsing diplomas of outside colleges which did not confer upon the graduate the actual right to practise medicine and surgery in the county where the diploma was granted. The report was referred to the Committee on Legislation.

TREASURER'S REPORT.

Dr. Porter read the report, which showed a deficiency of $541.

NEW PERMANENT MEMBERS:

Wm. C. Bailey, L. Bolton Bangs, Barnard Barton, C. E. Bruce, S. S. Burke, C. W. Crispell, John H. Cipperly, Andrew F. Currier, Francis Delafield, A. C. Drury, M. B. Holwell, J. H. Glass, G. M. Hammond, John H. Haffron, E. M. Hermance, F. W. Hinkel, Burke Pillsbury, Clarence C. Rice, Charles Storer, William G. Trecher, John T. Wheeler, Paul H. Kretzschmar, Geo. R. Fowler, R. A. Witthaus, W. B. De Garmo.

The by-laws of the Medical Society of the County of Jefferson were approved, with suggestions of certain alterations.

Dr. Lucian Howe read the

REPORT OF THE COMMITTEE ON BLINDNESS,

which was in accord with the paper he had read the day previous. Blindness in the State was rapidly on the increase; arose chiefly from purulent conjunctivitis in infancy, a disease spread largely by immigrants, especially the lower Irish. The cost of support of the blind in New York, in 1880, was over one million dollars, and would be about two million in 1888. The committee suggested the necessity for popularizing, among the lay public, the necessity for thorough cleansing of the eyes immediately after birth.

In institutions a small quantity of two per cent. solution nitrate of silver should be used. There should be quarantine of suspicious cases in institutions, and posters should be put up where people congregated, in workshops, etc., cautioning against contagious diseases of the eyes.

The committee was continued.

A resolution offered by Dr. Sniter, instructing the Committee on Legislation to frame a bill for presentation to the Legislature, regulating the use of embalming processes by undertakers, was passed.

SALE OF VOLUMES OF "TRANSACTIONS."

The income from sale of "Transactions" was small, and the Committee on Publication was instructed to report a plan of increasing the sales at the next annual meeting, either by changing form of publication or otherwise.

MANAGEMENT OF CARDIAC DILATATION BASED ON ITS ETIOLOGY.

Dr. A. L. Loomis, of New York, read the paper. Cardiac murmurs were now regarded as of significance according to the pathological lesions and functional disturbances which they attended.

When the circulatory system became disturbed by disease within, or aside from, the heart, there was tendency to compensating hypertrophy. To maintain such hypertrophy of the heart certain conditions must be complied with: (1) the muscular tissue of the heart must be healthy; (2) the heart-muscle must receive sufficient supply of healthy arterial blood; (3) waste products must be rapidly removed from the body; (4) the nerves of the heart must be in normal state. Any changes of these conditions led to weakening of the heart-muscle and favored dilatation.

In studying the etiology of cardiac dilatation, cases divided themselves naturally into two classes, primary and secondary. The primary causes were (1) impaired nutrition with extreme anæmia, as in those subject to excessive physical labor; (2) degenerative changes in the heart-muscle; (3) excessive use of narcotics, as tobacco, alcohol, excessive venery. Secondary causes were insufficiency of aortic and mitral valves, obstruction to aortic circulation, atheromatous changes in nutritive artery of the heart; arterial sclerosis, and renal disease. It was always important, from a therapeutic standpoint, to determine whether dilatation was or was not secondary to hypertrophy, for the chances of temporary or permanent relief were greatly diminished if it were secondary to hypertrophy. Dilatation from impaired nutrition, most common in hard-working men, should be treated by rest, diet (mostly animal food), moderate physical exercise. He had obtained benefit from only one drug, arsenic in one-sixtieth grain doses after meals. In dilatation after typhoid fever, and other acute infectious diseases, the patient should not be allowed to rise from bed; give suitable food, wine; give combination of quinine and strychnine. Attention to functions of stomach and liver. Small doses of calomel, combined with rhubarb and soda, diet, and rest, often did more to relieve symptoms than tonics. Iron, arsenic, and strychnine were the most useful tonics in cases of dilatation from fatty degeneration.

The general management of dilatation due to fibroid degenerations of the heart-muscle was similar to that in fatty degeneration. Bichloride of mercury was administered in one-sixth grain doses for a long period; so-called cardiac tonics to be avoided; maintain action of the kidneys. Dilatation in those addicted to excesses with tobacco, venery, etc.; remove the exciting cause; use of strychnine and shower-bath; bromide of potassium in cases of excessive venery.

In secondary dilatation the condition was more serious. The heart-muscle should be kept as healthy as possible by diet and general habit; when compensation was incomplete digitalis was demanded. Digitalis was safely administered when pulse was of high tension and its use was followed by increased urinary secretion. Some of the indications for convallaria, strophanthus, etc., were pointed out.

Dr. A. Jacobi spoke of cardiac dilatation due to certain forms of insufficient development of the arteries. Spartein was very useful where speedy effect was desired, and digitalis produced cumulative effects.

Dr. Stoddard continued the discussion, laying stress upon the contra-indications in the use of digitalis.

PRACTICAL APPLICATION OF ACOUSTICS OF THE HUMAN CHEST IN PHYSICAL DIAGNOSIS (part 2)

Dr. James R. Leaming, of New York, stated that this

paper constituted the second part, the first part having been read before the New York Academy of Medicine, December 6, 1888. Primary sound vibrations may be conducted or consonated. Reflection of sound is the opposite of conduction, and, in a sound chamber prevents sound leakage. In the human chest the pleural lining reflects equally from all directions, but when adhesions were present, or tumors caused pressure upon it, leakage took place. Echoes are reflected sound-waves, either parallel or converging. Reflected sounds pertain altogether to sound-waves, and consonation has also to do with sound-waves alone, and nothing to do with primary or conducted vibrations. Consonation is constantly made use of by the auscultator. If the vital process be interfered with by paresis of the enveloping muscular fibres of the alveoli, which takes place in emphysema, the muscular sussurrus, the true respiratory murmur, will not be heard; when disability is temporary its gradual return can be noticed. In centric pneumonia there is no other physical sign than slightly raised pitch under percussion, but when the pneumonic process reaches the pleura physical signs immediately manifest the fact; at once are heard interpleural râles and bronchial breathing. Sound conduction, established by extension of disease to the pleura, revealed the lung consolidation. The sounds consonated in the air-sac were: First, from outside; second, air-friction sounds, caused by mucus, etc. The author then applied laws of acoustics to the heart in disease. The intervals of silence of heart-sounds must remain in exact synchronitic proportion so long as the heart remains in perfect mechanism as a pump. As soon as the heart-rhythm is altered its extent will measure the amount of injury the heart has received, and then murmurs of obstruction and regurgitation will define the locality and nature of the disease. The study of the individual heart-sounds was then taken up.

THE ETIOLOGY OF CROUPOUS PNEUMONIA.

DR. GEORGE M. STERNBERG, U. S. A., read the paper, which was a review of bacteriological investigations in this direction.

The evidence was pretty conclusively in favor of the microbe first discovered by the author in 1880, which he named after Pasteur, as being the cause of croupous pneumonia. Inoculations in rabbits, mice, etc., and examinations for the microbe in croupous pneumonia, furnished the evidence presented in favor of this view of the etiology of the disease.

DR. A. L. LOOMIS discussed the paper from the standpoint of the clinician, and said he knew no reason why, if microbes produced pneumonia, they should always be of but one species. It would seem reasonable that the disease occurring in connection with diphtheria and other affections might be the result of the influence of germs which produced the primary affection.

DR. THOMAS E. SATTERTHWAITE said the causation of other forms of pneumonia could readily be accounted for, but not so with acute lobar pneumonia. He thought the evidence was in favor of its being a microbic disease.

AFTERNOON SESSION.

REPORT OF COMMITTEE ON THE PRESIDENT'S INAUGURAL ADDRESS.

DR. POTTER read the report, which recommended referring that portion on the responsibility of medical commissioners in lunacy to the Committee on Legislation; that the question of the division of the Society into sections be left to the Business Committee from year to year; that the Publication Committee be instructed to incorporate into the Transactions each year a list of all former officers with their terms of service.

DR. FOWLER, of Brooklyn, reported

A UNIQUE CASE OF HERNIA OF THE PLEURA IN THE NECK.

It occurred in an illy-nourished infant, the hernial tumor developing after severe coughing during a bronchitis. There were two well-marked tumors of the neck, one on either side the trachea, reaching to the inferior maxilla, nearly disappearing on inspiration, tense on expiration. The child subsequently died of acute bronchitis, and at autopsy the tumors were found to have resulted from rupture of a primary bronchus at the upper part of the right lung, allowing air to escape beneath the pleura, which became stripped from its attachments.

THE PRESIDENT then read his address (see page 144), for which the Society extended a vote of thanks.

DR. H. R. HOPKINS, of Buffalo, then read a paper on

BASEDOW'S DISEASE,

and discussed particularly the symptoms connected with (1) the heart, (2) the thyroid gland, (3) the eyes. A point in prognosis related to inordinate action of the heart when this organ was undergoing fatty degeneration. Such cases were likely to prove speedily fatal.

The paper was discussed by Drs. Dana and Jacobi.

DR. C. L. DANA, of New York, read a paper entitled,

CHRONIC HEADACHE.

It was based on a study of two hundred cases of chronic headache, functional in character, excluding migraine. His conclusions were: 1. There should be more general recognition and differentiation of chronic head pains of functional origin. 2. Pains in the head are either neuralgias, migraines, or so-called headaches. 3. The seat of headaches is always in or referred to the trigeminal, vagus, or four upper cervical nerves. 4. Headaches are seated in or referred to the periphery of the nerves in question; neuralgia is seated in the trunks or central; migraine is a periodical discharging neurosis, affecting motor, vaso motor, secretory, as well as one or more cranial sensory nerves. 5. The dura mater is the most frequent seat of headache. 6. The great headache ages are from eight to twenty-five, and again from thirty-five to forty-five; childhood and old age are exempt. 7. The chronic functional, non-migrainous headaches may be classified as hæmic, including diathetic forms, toxic, dyspeptic, neurotic, reflex.

More exact knowledge of the nature of headaches may be gathered by studying the location and character of the pain in its relation to cause. Neurotic headache is best treated symptomatically by antipyrin, menthol, antifebrin, caffein, and bromides. Headaches due to reflexes are often treated better constitutionally than by means directed to local conditions. Rheumatic headaches were best treated by ammonia, chloral, and warmth.

DR. L. S. PILCHER, of Brooklyn, read the next paper entitled,

A CONTRIBUTION TO THE SURGERY OF CEREBRAL TUMORS,

in which he gave the history of a case of injury by fall to the skull of a man who, two years afterward, had epileptic attacks and mental impairment, which led him to use the trephine. A cerebral tumor was diagnosticated which could not be definitely located from the symptoms, but was believed to be in the angular gyrus or its immediate vicinity. It was not discovered after removing three pieces of bone, making an opening of considerable size. A portion of brain which projected forcibly through the opening could not be pressed back; it was sliced off, and the pieces of bone replaced. Paralysis of right arm and leg was noticeable after the operation, and the patient died within thirty-eight hours from respiratory failure. One of the pieces of bone had already become adherent to the dura. A gliomatous mass occupied the anterior half of the left hemisphere, extending into the corpus callosum. It could not have been removed had its location been known before the operation.

THE USE OF GALVANISM IN GYNECOLOGY,

was the title of a paper by DR. FORD, of Utica, and was supplementary to some he had read previously on this subject. He called attention to the fact that the galvanic

current of great voltage was safer in cases of fibroids, and seemed most efficacious, while the greatest electrolytic action was obtained from small voltage with high amperage. During 1888 he had employed galvanism in about sixty-four cases, including fibroids, exudates, hydrosalpinx, etc. In pelvic exudates it seemed of much value.

Dr. Daniel Lewis read the

REPORT OF THE COMMITTEE ON QUARANTINE CONTROL.

The question for the consideration of the committee had been whether it was best to take control of quarantine at New York Harbor from the State of New York and invest it in the Marine Hospital service. The extensive improvements now in progress at the quarantine stations met all the more important criticisms of the Philadelphia committee which visited the islands when cholera was there. With proper agitation, particularly by the physicians of the State, demands for sanitary reforms would be met by the Legislature, and the committee, believing in "home rule," did not approve of investing quarantine control in the Marine service.

Dr. J. H. Glass, of Utica, read a paper upon,

INFERIOR DENTAL NEURECTOMY,

describing a new operation—the removing of a portion of the inferior dental nerve from within, instead of externally to the mouth. The objections to the external method were well known. In the one case he removed five-sixteenths of an inch of the nerve. The patient had not yet had a return of the neuralgia. He had further demonstrated the practicability of the procedure on the cadaver.

The annual dinner was served at the Delavan, at 7 P.M.

PAPERS BY TITLE.

The following papers were read by title: "On the Use of Sulpholeate of Sodium in the Treatment of Skin Diseases," by Dr. Geo. H. Fox; "The Medical Treatment of Diseases of the Urinary Organs in Children," by Dr. A. Jacobi; "Amblyopia in Diabetes, with Report of Six Cases," by Dr. W. O. Moore; "On the Use of Tobacco," by Dr. F. H. Bosworth; "The Use of Prismatic Spectacles for the Relief of Asthenopia caused by Insufficiency of the Ocular Muscles—Cases," by Dr. David Webster; "Biographical Sketch of Dr. Hyde, and also one of Dr. Jewett," by Dr. W. C. Wey; "Double Inguinal Hernia in a Pseudo-Hermaphrodite—Operation," by Dr. C. N. Dixon Jones.

Third Day, Thursday, February 7th—Morning Session.

OFFICERS-ELECT FOR ENSUING YEAR.

After the transaction of some preliminary business, the Committe on Nomination reported as follows: For *President*, Daniel Lewis, of New York; *Vice-President*, Alfred Mercer, of Syracuse; *Secretary*, F. C. Curtis, of Albany; *Treasurer*, C. H. Porter, of Albany.

Censors, Southern District: L. Emmet Holt, of New York; S. Sherwell, of Brooklyn; E. M. Hermance, of Yonkers. Eastern District: Joseph Lewis, of Albany; Thompson Burton, of Fultonville; Leroy McLean, of Troy. Middle District: Robert Frazier, of Camden; C. L. Stiles, of Owego; J. H. Glass, of Utica. Western District: H. L. Elsner, of Syracuse; Frank H. Patten, of Buffalo; B. R. Fordyce, of Union Springs. College of Medicine of Syracuse University, J. N. Goff, of Cazenovia.

Committee of Arrangements: Samuel B. Ward, of Albany; Edward L. Partridge, of New York, and C. S. Merrill, of Albany. *Committee on By-laws:* F. A. Castle, of New York; H. R. Simmons, of Utica, and F. C. Curtis, of Albany. *Committee on Hygiene:* E. V. Stoddard, of Rochester; A. N. Bell, of Brooklyn; Wm. B. Brown, of Bath; J. P. Creveling, of Auburn; Wm. H. Bailey, of Albany; Wm. C. Bailey, of Albion; E. F. Brush, of Mt. Vernon. *Committee on Legislation:* D. B. St. John Roosa, of New York; Burke Pillsbury, of Middletown; Maurice J. Levi, of Albany. *Committee on Ethics:* A. Jacobi, of New York; Arthur Mathewson, of Brooklyn; H. R. Hopkins, of Buffalo. *Committee on Prize Essays:* Geo. F. Shrady and F. P. Foster, of New York; Eugene Beach, of Gloversville. *Committee on Publication:* F. C. Curtis, of Albany; John O. Roe, of Rochester; O. B. Douglas, of New York, and C. H. Porter, of Albany.

Honorary Members: Howard Marsh, of London; Francis Bacon, of New Haven; Reginald Harrison, of Liverpool; Morell Mackenzie, of London; William Pepper, of Philadelphia; Max Schede, of Hamburg.

Eligible Honorary Members: William H. Taylor, of Cincinnati; Joseph Price, of Philadelphia; George J. Engelman, of St. Louis; R. J. Levis, of Philadelphia; Lennox Browne, of London; James Nevins Hyde, of Chicago; E. E. Montgomery, of Philadelphia.

Delegates to other Societies: To British Medical Association, Robert Abbe, of New York; E. L. Partridge, of New York; L. D. Bulkley, of New York; William Hailes, of Albany. To Canadian Medical Association, Floyd S. Crego, James MacFie, and G. H. Oliver. To Ontario Medical Association, John Gerin, J. F. Whitbeck, James P. Boyd, W. W. Potter, H. G. Dubois, L. D. Weigel, G. M. Hammond, W. B. DeGarmo. To Connecticut State Medical Society, D. B. St. John Roosa, J. P. Creveling, Andrew F. Currier. To Massachusetts Medical Society, A. M. Phelps, O. B. Douglas, John O. Roe, L. G. Weigel. To New Jersey Medical Society, Walter B. Chase, Thomas E. Satterthwaite. To Pennsylvania Medical Society, C. L. Dana, H. D. Chapin. To Virginia Medical Society, C. C. Rice, George H. Fox, A. M. Phelps.

RESIGNATION OF SECRETARY DR. W. MANLIUS SMITH.

The Nominating Committee had received the declination of Dr. William Manlius Smith, to serve the Society longer as secretary. The Committee expressed its deep regrets, and paid a high compliment to Dr. Smith for his valuable services to the Society during the twelve years he had been Secretary. All the gentlemen named for office were elected without opposition, excepting Dr. Goff, nominated for Censor of Syracuse University. Speaking for the faculty of that college, Dr. W. M. Smith, nominated Dr. G. V. Stoddard. Dr. Goff received eight votes, Dr. Stoddard, seven. Dr. Flood read a resolution to change the by-laws, to be acted on next year, requiring but a two-thirds vote of the Nominating Committee, instead of a full vote, to make the nomination for President, Vice-President, Secretary, and Treasurer. Majority vote for other officers.

A committee of three, consisting of Drs. Flood, Curtis, and Brown, was appointed to consider the revision of the constitution of the Society.

Dr. L. D. Bulkley read a paper on "Clinical Study of Alopecia Areata." After a vote of thanks to the President for the able and courteous manner with which he had presided over their deliberations, the Society adjourned.

The Alkaloids of Cod-liver Oil.—Gautier and Mourgues have found in cod-liver oil six toxic leucomaines; butylamine, hexylamine, amylamine hydro-dimethyl pyridine, aselline, and morrhuine.

Aselline is not abundant, and only acts in large doses, producing stupor, fatigue, and dyspnœa. Three milligrammes of the chloro-hydrate killed a green finch in fifteen minutes.

Morrhuine is quite abundant, as a teaspoonful of dark oil contained two milligrammes. Given to guinea-pigs and to birds, as a chloro-hydrate, it proved stimulant, diaphoretic, and especially diuretic, a guinea-pig weighing 250 grammes having lost 13.5 grammes in two hours, after taking 29 milligrammes of the alkoloid hypodermically.—*Medical Times.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 28, 1889.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. HENRY D. CHAPIN read a paper entitled,

SEPTIC POISONING IN EARLY LIFE.

The extreme susceptibility to septic infection manifested in early life had long been recognized by those called upon to treat the diseases of children. A division of the cases was made into septic poisoning which occurred in the newly born, and that seen in older infants and young children. Infection might even take place before birth by the passage of septic matter from the mother to the fœtus through the medium of the placenta. In such cases the infant might be born dead, or die soon after birth.

After birth the chief vulnerable point for the entrance of septic poison was the umbilicus. Dr. J. Lewis Smith, the author said, had divided these cases into two classes: Those in which the poison entered the system through an umbilical sore and was conveyed by the lymphatics, and those in which it entered by the umbilical vein. When the accident took place there was more or less oozing of fluid from the point of entrance, soon followed by evidence of pleurisy, peritonitis, and other results of such infection. An illustrative case was cited in which the infant was born healthy, but the mother contracted septicæmia, and five days after birth the infant showed erysipelas upon the body, followed soon by death. The autopsy showed peritonitis; pus in the liver, none in the umbilical vein, greatest amount of inflammatory process at the navel. A simple abrasion elsewhere on the body might be the seat of entrance for the poison. The abrasion might be caused by the forceps. In one of his cases the infant on the sixth day showed erysipelas, commencing at the vulva. General septic poisoning followed, with inflammation of the serous membranes and death. In fact, the genitals became, after birth, the most vulnerable point for the entrance of the septic poison. As the infant grew older the upper part of the body, particularly the scalp and mouth, not infrequently became the seat of invasion. The cells, by their inherent vitality, could dispose of and destroy a certain number of the invading germs, but if the germs were produced in too great number the poison found its way into the general system, producing septicæmia. Not infrequently the infection took place from ulcers of the scalp caused by the presence of pediculi and scratching. The author cited a case in which swelling and ulceration of the glands of the neck and some septic symptoms in a girl, aged seven, apparently owed their development, in the first place, to head-lice. Cleanliness effected a cure.

The mouth would seem to be a particularly favorable place for bacterial development. Aphthous patches, when they formed small ulcers, were favorable for the entrance of septic matter. The pain and distress, together with constitutional symptoms, attending many cases of stomatitis could hardly be explained by simple inflammation of the mucous membrane, but neighboring tissues being infiltrated by septic matter would satisfactorily account for the disturbance. Many cases of septic disturbance in the mouth had their origin in carious teeth.

Other sources of septic poisoning were in nasal catarrh, otitis media purulenta, etc. He believed many cases of so-called scrofulous diathesis were cases of constitutional poisoning, the poison entering at some lesion which had been overlooked. Infection of the general system might not take place at once, but after a time the local lymphatics became unable to dispose of the germs and general infection resulted. The intestinal tract might be the entrance for the poison, and he believed a common entrance was in the air-passages, which were constantly exposed to septic influences in the foul air of close tenement-quarters. The symptoms here were different from those seen in malaria from marsh miasm, although the diagnosis of malaria was common.

The treatment was preventive, local, and constitutional. Cleanliness was of special importance. The cord in the newly born should receive the dry dressing, to hasten mummification. One should search for lesions and heal them by approved methods of treatment.

DR. J. LEWIS SMITH approved of the division of the cases into those in which the sepsis occurred in the newly born and those of older children. In the former, the cases most likely to prove fatal were those in which the sepsis took place through the umbilicus, which might be by way of the lymphatics at the umbilical fossa, or by way of the vein. He recited some of his observations in an outbreak of eight cases in the Infant Asylum a year ago, and already published. Aphtha of the mouth so readily healed that he doubted whether this could be considered one of the sources of sepsis. He dwelt on the lesions of scarlet fever and diphtheria as sources of entrance for septic matter, and expressed the belief that such septic complication of the cases was often the cause of a fatal termination. It was coming to be a common practice in diphtheria to administer small doses of bichloride of mercury, and Dr. Smith recommended its use in a spray, a certain number of compressions of the bulb to spray a teaspoonful of the liquid which contained the required dose of the bichloride. Thus the local antiseptic effect of the drug was first obtained in the throat, and afterward the child swallowed it. He also called attention to the great benefit to be derived from vapor in the room, from a solution of carbolic acid, turpentine, oil of eucalyptus, and water. The oil of eucalyptus covered the objectionable odor of the other two ingredients.

DR. A. H. SMITH pointed out the advantages of stripping the cord of all gelatinous material before dressing. It hastened mummification.

DR. A. F. CURRIER said the diseases of the eyes to which newly born infants were subject had been much less frequent in institutions in which a solution of nitrate of silver had been regularly employed as a prophylaxis.

DR. CHAPIN remarked, in closing the discussion, that it was not within the scope of the paper to speak of sepsis from the poisons of scarlet fever, diphtheria, and gonorrhœa.

DR. SIMON BARUCH then read a paper entitled,

THE VALUE OF WATER IN THERAPEUTICS.

The author contrasted the present position of water as a therapeutic agent with that formerly occupied by it, compared methods now in vogue with those of the past, and drew lessons verified by clinical experience. Most text-books devoted little space to water as a therapeutic agent.

His first experience with the use of water externally took place when he was army surgeon in the civil conflict. It was customary at that time to use water freely on wounds, and the results compared very unfavorably with those from the modern dry method; suppuration and mortification were common. Experience had demonstrated the value of boiled water in laparotomy, and also the fact that drugs added to render the water antiseptic would be less called for if the water were clean and boiled before using.

The application of water as a styptic was of modern origin. In post-partum hemorrhage, for instance, intra-uterine irrigation by hot water was much superior to persulphate of iron, which formerly was much used. Strict cleanliness and hot water at the time of the operation would be the antiseptic of surgery in the future. We were now in a position to appreciate the value of hot vaginal douches introduced by Dr. Emmet in place of zinc solutions, etc., in certain inflammatory processes. While speaking of the value of water employed externally the author mentioned certain skin-diseases, but pointed out eczema particularly as contraindicating its use. It

was also contraindicated in suppurating otitis media, a disease in which much better results had been obtained by substituting the dry boracic-acid dressing. Time had also shown that in normal labor vaginal injections, once commonly practised by some, were contraindicated. The author cited some cases in practice in proof of his deductions.

Passing to the internal use of water for other than diuretic and diaphoretic effects, he first took up its employment in dyspepsia, both recent and chronic, citing cases in which marked benefit had been derived. In recent cases washing the stomach would often bring about a cure in a very short period, while in chronic ones longer time was required, and the remedy had to be supplemented by stricter diet, and perhaps by drugs. The sipping of hot water some time before breakfast was also of benefit in some cases. Washing the stomach had been employed with success in gastric and gastro-intestinal disturbances of infants, and free irrigation of the stomach for ileus was a remedy which should be resorted to before laparotomy. Dr. Baruch could testify to the good effects of irrigation of the intestine in catarrhal jaundice, but this treatment had proved a failure in his hands in jaundice from gall-stones, although others had reported success. In summer diarrhœa it lessened the number and changed the character of the movements, and arrested purging.

Cold water acted on the human body chiefly by mechanical and thermal influence. By its use changes could be wrought in the innervation of different parts, and in the circulatory system to the extent of producing only slight contraction of the blood-vessels or of causing absolute death by shutting off all circulation. The agent was beneficial when applied to the surface in proportion to the reactionary powers of the patient. The application of such briefly stated principles might be left to each practitioner, but Dr. Baruch mentioned chronic diseases involving faulty nutrition as those in which the external application of cold water afforded much satisfaction, especially in robust patients who reacted well under drying and friction after the cold bath; and in gastric and cardiac neurasthenia it went far toward restoring the health. The wet sheet involved the presence of a competent assistant, but sometimes promoted reaction better than the bath. In some chronic diseases the applications should be local. As the internal use of hot water had enabled him to dispense largely with such palliative remedies as pepsin, so had the external application of cold water enabled him to dispense largely with so-called tonic medicines. Cold water to reduce the temperature, and to stimulate the nerve-powers to reaction from shock produced by cold upon a large surface, had obtained a wide application, as in hyperpyrexia from sunstroke, rheumatic fever, typhoid fever, etc. The author dwelt upon the greatly lessened mortality in typhoid fever in cases where the temperature was kept down by cold or tepid water, as shown by Brandt's statistics and others. The percentage of deaths in typhoid fever in this country was little better than that recorded in Germany and elsewhere when the application of water to the surface was not practised; it was about twenty-one to twenty-six per cent., whereas under the use of cold or tepid water it had fallen to seven or below. Dr. Baruch had become convinced that the ordinary treatment of typhoid fever should give way to the hydropathic method.

Dr. J. Harvie Dew continued the discussion of this subject in a short paper, impressing its importance more especially from a physiological stand-point. The following facts should first be noted: 1. The chief component part of the human body in health was water; its relative proportion to all the solid constituents had been estimated to be two-thirds or three-fourths the entire weight of the person. 2. Water constituted almost the total volume of each one of the circulating fluids, including that of those of digestion. 3. It was the essential medium by which digestion was accomplished, absorption made possible, and the transportation of the elements of nutrition to the various tissues of the body was made easy. 4. As water entered so largely into the composition of the tissues it became of corresponding importance to every process in assimilation. 5. Water was the medium by which all waste matters were held in solution and conducted to their several points of exit. 6. Observations and experiments had shown that from three to four pints of liquid food were required to maintain normal functions and weight in an individual weighing one hundred and forty to one hundred and fifty pounds. 7. It was a clinical fact that persons thin in flesh were by habit, or for other reason, accustomed to take very small quantities of liquid food, while well-preserved and fleshy persons were copious drinkers of fluid in one form or another. 8. It was also a clinical fact that in every morbid or diseased condition of the system, whether organic or functional, the functions of digestion, absorption, assimilation, secretion, and excretion, embracing elimination, became in some way disturbed—sometimes one or more of these functions, at others all of them, to a greater or less degree in the same patient.

It thus became evident that water in its various applications was of extreme importance in the treatment of disease and the restoration of the normal functions of the body. Many physicians objected to the use of water at meals, seeming to forget that it was rapidly absorbed and took the place in the circulatory fluids of the large quantity of water which these gave up during the digestion and absorption of the food in process of consumption. Water or liquid food was seldom taken in excess, but many persons took too little and suffered from deficiency in weight, dyspepsia, constipation, tenacious secretions, dryness and other disturbances of the skin, defective elimination, and all the symptoms brought about in consequence of such disturbances of normal function. The physician should always make careful inquiry as to how much his patients were taking of liquids in one form or another, and he would often be surprised to find that persons who should be eliminating from three to five pints were consuming but one to two pints.

Dr. Andrew H. Smith moved that, owing to the importance and scope of the subject treated of by the last two papers, its discussion be made the special order of the next meeting. Carried.

Dr. G. H. Fox was elected censor to fill a vacancy, and Dr. E. S. Peck was appointed to fill a vacancy in the Committee on Ethics.

NEW YORK NEUROLOGICAL ASSOCIATION.

Meeting held January 8, 1889.

George W. Jacoby, M.D., President, in the Chair.

Dr. Graeme M. Hammond exhibited a male patient with

TRAUMATIC HYSTERIA.

He had been injured July 11, 1885, by falling upon a sharp-pointed iron rod one inch in diameter, which penetrated into the right submaxillary region about one and one-third inch from the median line. It passed in about four inches in a direction upward, backward, and inward. Dr. Philip Zenner, of Cincinnati, saw the patient half an hour subsequent to the accident, and has described his symptoms in The Medical Record. He was then suffering from paralysis of the right arm and leg, right side of the face, tongue, and palate. There was complete anæsthesia of the left side of the face, and loss of taste on left side of tongue, and of smell in the left nostril. There was intense pain in the region supplied by the middle division of the fifth nerve. He consulted Dr. Hammond for the relief of this pain, and his advice was, to excise the middle division of the nerve. The patient was sent by him to St. Luke's Hospital, where Dr. Robert Abbe operated November 16th. The nerve was excised almost to Meckel's ganglion. The next

day the patient was again examined. The intense facial pain had disappeared, and the anæsthesia of the two other divisions of the fifth had also disappeared. The senses of smell and taste were restored, and the hemiplegia was markedly improved. At the present time, seven weeks after the operation, there has been no relapse. Dr. Hammond's conclusion was: that although a certain amount of organic lesion was undoubtedly present, yet the fact that so many symptoms were relieved by an operation which would not have affected them at all if they had been produced by a central lesion, showed conclusively that hysteria must be regarded as the sole cause of their production.

Dr. C. L. Dana asked if the whole of the side of the tongue was affected, and was anwered in the affirmative. He stated that he had seen the patient previously, and that the gain in motor power since the operation was little; that there was still considerable loss of power and rigidity. There was no doubt that he had a genuine trauma at the base of the brain, and that he now has an organic lesion upon which some hysteria is superimposed.

Dr. Frederick Peterson did not think that a true ankle clonus, such as was obtained in this case, could be obtained in simple and pure hysteria. He had not met with true clonus in hysteria, but had frequently observed what Gowers describes as a spurious clonus, due to a half-voluntary contraction of calf-muscles, and which Gowers considers characteristic of hysteria.

Dr. B. Sachs believed that an actual clonus is observed in pure functional neuroses at times, and stated that such cases are cited by Oppenheim. He thought the marked hysterical element in this case and the rapid improvement made it possibly one of hysteria. He asked if there were any hysterical symptoms in the previous history of the case, and was answered in the negative.

Dr. Hammond closed the discussion by saying he thought there was a real organic lesion also in the case, but that the anæsthesia, part of the hemiplegia, and the loss of taste and smell were hysterical.

Dr. Isaac Ott, of Easton, Pa., then read a paper upon the

THERMO-POLYPNŒIC CENTRE AND THERMOTAXIS,

the following being his conclusions from sixty experiments:

1. The thermo-polypnœic centre is situated in the gray matter about the third ventricle at its anterior part.

2. This centre acts reflexly, so that when heat is thrown on the body the sensory impulses excited by the heat are conveyed to the polypnœic centre, which stirs up the respiratory centre to throw off heat. It stands between heat-production on one side and heat-dissipation on the other.

3. The fall of the number of respirations by the heat after the removal of the polypnœic centre is due to an excitation of fibres running in the vagi which inhibit the respiratory centre.

4. The normal temperature of the body is not necessarily dependent upon the amount of heat produced or dissipated, for human calorimetry shows that the heat-production varies, but the temperature remains nearly the same. The relation of heat-production to heat-dissipation decides the temperature.

5. The cortical centres, the cruciate and Sylvian, are thermotaxic.

6. The four basal thermotaxic centres are situated as follows: one in the caudate nucleus, one in the gray matter beneath the caudate nucleus, another in the gray matter about the most anterior part of the third ventricle, and still another in the anterior inner end of the optic thalamus in the gray matter about the third ventricle.

7. These six thermotaxic centres are more circumscribed than Dr. Gerard, of Genoa, believes.

8. These six thermotaxic centres are neither thermo-inhibitory nor thermo-excitor, but thermotaxic; that is, they maintain the balance between heat-production and heat-dissipation, so that the temperature is kept normal.

9. In fever neither increased production nor increased dissipation nor high temperature are necessary, but fever is mainly a disease of thermotaxis, a disorder of the four basal thermotaxic centres. It is true in septic fever that in its initial stage heat-production usually runs temporarily ahead of heat-dissipation, but exceptionally both are immediately diminished.

10. Antipyretics do not necessarily inhibit or excite heat-production or heat-dissipation, but act upon the thermotaxic centres disordered by fever agents to restore order or normal thermotaxis. Professor Chittenden's careful researches prove that in healthy hungry rabbits moderate doses of quinine exercise at most only a very slight depressing influence on body temperature, and have but a minimum effect upon the production of carbonic acid.

11. D'Arsonval's calorimeter for animals and man, as modified by the writer, is less liable to error than any other, as the agitator can be worked without opening the instrument or hardly disturbing the sawdust covering.

12. Human calorimetry shows that an adult, after a full meal, produces between three hundred to four hundred heat units per hour, and not one hundred and ten calorics, as Helmholtz theoretically obtained.

Dr. Dana did not question the truth of the author's statements, but what interpretation should we make of the six thermotaxic centres he had described? Can the bodily temperature be regulated without them at all? He referred to a case of his that he had recently published, where, although there was no cerebrum, basal ganglia, or cerebellum, and only part of the pons, yet the temperature was normal. The facts of human pathology should be brought into harmony with these physiological experiments.

Dr. Ott said it was difficult to understand the regulation of temperature in Dr. Dana's monster. Injuries to the corpus striatum disturb the temperature, but the other thermotaxic centres serve to regulate it.

A paper was then read by Dr. H. W. Berg on

ECLAMPSIA INFANTUM IN ITS RELATION TO FEVER,

in which he took the ground that febrile eclampsia calls into activity two sets of nerve-centres, the thermogenic and the convulsive. An alteration or lesion is produced in the thermogenic centre by excessive hyperæmia, anæmia, or some minute structural change, causing a rise of temperature; secondarily, it affects the unstable convulsive centre in the medulla, especially in infants whose medullæ are in an exalted state of irritation. He thought it probable that the motor and thermic nerves are intermingled in the medulla, and thus an irritation of one results in irritation of the other. Thus fever produces convulsions in children, while the process may at times be reversed, as in the status epilepticus, where, after a period of convulsion, the temperature begins to rise, and, as Bourneville has pointed out, may reach an enormous height. He would treat febrile eclampsia, not with antispasmodics, but with antipyretic remedies; in other words, treat the cause of the convulsions. In this he has had gratifying success in the use of antipyrine and antifebrine, together with cold or tepid sponging with equal parts of water and alcohol.

Dr. Ott said that children no doubt have feeble thermogenic centres.

Dr. William Leszynsky referred to a report of his, some years ago, of twenty or more cases of status epilepticus, in which the rise in temperature did not accord with the statements of Bourneville. As to treatment, he thought simple sponging with alcohol and water sufficient, and that the use of the wet pack or of antipyretics was objectionable.

Dr. Weber would ask Dr. Ott if antipyrine and phenacetine act by assisting the system in the dissipation of heat.

Dr. Ott stated that antipyrine probably decreases heat-production and increases heat-dissipation. The same would be true of phenacetine.

Dr. Weber thought that dependence must not be

placed upon antipyretics in severe cases of infantile eclampsia. Chloroform should be administered by inhalation, or chloral injected per rectum. He had seen cold water injected with success.

DR. SACHS did not believe the relation of eclampsia and fever exactly that of effect and cause. Were convulsions due to high fever it would be curious that in a fever preceded at its outset by convulsions, although the temperature continues high or increases, yet there were no subsequent convulsions. The fever in epilepsy was not due to excessive muscular exercise. A case of his with hystero-epilepsy had recently had as many as two hundred convulsions in twenty-four hours, but without any elevation of temperature.

DR. HARWOOD had treated eclampsia with chloroform and with the wet pack, and could heartily endorse the conclusions of Dr. Berg as to hydrotherapeusis.

DR. BERG, in closing the discussion, said he thought the instance cited by Dr. Sachs, of a fever ushered in by convulsion, yet without further eclamptic seizures, in spite of the continuance of the fever, did not carry as much weight with it as would at first appear. Hughlings Jackson had pointed out that the convulsive centres could become so exhausted that the fits would not be repeated. He prefers the wet pack even to sponging, because refrigeration by the former method is more rapid and less dangerous. He had seen pneumonia produced by sponging. The pack is less harmful.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DISCUSSION ON CHOREA AT THE MEDICAL AND CHIRURGICAL SOCIETY—PAPERS BY DRS. HERRINGHAM AND GARROD—SPEECHES BY DRS. CHEADLE, SANSOM, STURGES, BARNES, STEPHEN MACKENZIE, AND ROBERT J. LEE—CHANGES AT THE UNIVERSITY OF LONDON—LEGAL DIFFICULTIES AS TO THE COLLEGE BUILDINGS ON THE EMBANKMENT—THE WEATHER OF 1888 AND THE REDUCED DEATH-RATE.

LONDON, January 14, 1889.

CHOREA formed the subject of discussion at the last meeting of the Medical and Chirurgical Society. Dr. Herringham read a paper based upon a study of the antecedents, family history, state of the heart, and subsequent history of eighty cases. In nineteen cases the attack had been preceded by acute rheumatism, and the total number of cases in which rheumatism could be traced was thirty-seven. Injury, shock, or violent emotion preceded the attack in six cases, the interval being never greater than two days. In twenty cases there was a history of hard mental work or worry. These influences were not mutually exclusive, since all those classed under injury, shock, or emotion could alone be considered as exciting, the others only as predisposing cases. In twenty-five cases none of these influences could be traced, and of this number fourteen were first attacks. Nearly all the patients were delicate, headaches and indigestion being common complaints. An inquiry into the family history (confined to parents, brothers, and sisters) showed that rheumatic fever had occurred in twenty-five out of seventy-five families; seventeen of these belonged to thirty-four patients of the rheumatic classes and the remaining eight to forty-one patients with no history of rheumatism. Chorea had occurred in twelve families, and nine of these were also rheumatic. With regard to the state of the heart, in ten cases it was normal, in twenty-five there was a doubt as to endocarditis, while in twenty cases the heart was certainly diseased. Thirty-seven cases were seen again, usually at an interval of two years or more, and for the most part presented the same state as before. Of eleven cases which developed signs of heart-disease during the attack of chorea, five were re-examined, and two of these were healthy while three gave good evidence of heart-disease. Dr. Herringham said he had arrived at the following conclusions from his observations, viz., that a large number of choreic patients are liable to rheumatism; that choreic patients are nearly always of a delicate constitution; that chorea is sometimes directly caused by emotion; that it may cause permanent heart-disease; and that it also gives rise to signs of heart-disease which are not permanent.

Dr. Archibald Garrod then read a paper (based upon eighty consecutive cases) dealing with the relation of chorea to rheumatism. Sixty-one of the patients were females and only nineteen males. There was a history of rheumatic fever in the near relations of twenty-six patients, of rheumatism with swollen joints in those of three, and of rheumatism in three more, making a total of thirty-two with rheumatic family histories. The total number of cases in which there was a personal history of rheumatic manifestations other than endocarditis was thirty-six. Dr. Garrod suggested that some cases in which there was no family history of rheumatism and no personal history of joint pains were nevertheless of rheumatic origin, and he quoted cases of rheumatic patients who had previously suffered from chorea, of the development of erythema nodosum and arthritis in the course of apparently non-rheumatic chorea, of chorea with endocarditis and nodules without joint pains, and of the association of acute pericarditis with chorea. In fifteen cases the attack was attributed to fright, but in some of these it was found on inquiry that the fright followed the onset of the chorea. A definite cardiac murmur was heard in forty-five cases, and in six others the first sound was murmurish. In some instances the murmurs developed under observation. The author expressed the opinion that the endocarditis of chorea was probably always of rheumatic origin, but that we had no evidence to show that all chorea was of rheumatic origin, a considerable number of cases being probably due to emotional and other causes.

Dr. Cheadle remarked that rheumatism was something much larger than arthritis. He thought Dr. Herringham had in some points based his inquiries on too narrow a definition of rheumatism, and also he was obliged to neglect those cases in which rheumatic arthritis followed chorea. Truly rheumatic symptoms in children were often very slight and transitory. He was surprised that Dr. Herringham had found fright or emotion a cause in only six cases. He had himself noticed the case of a rheumatic child who had had chorea and had recovered completely; it was taken to the pantomime, and the next day had a violent attack of chorea. Chorea went along with an unstable nervous system, and in a family it was often noticed that the unstable one was the rheumatic. He was inclined to think that much more chorea was rheumatic than was generally supposed, and the absence of a history of arthritis was not to be taken as a proof that the case was of non-rheumatic origin, for the rheumatism might have been overlooked, or might have come on after the chorea.

Dr. Sansom said his experience led him to believe that there was a fright-chorea dissociated from rheumatism. He admitted, of course, that rheumatism was a cause in many cases, but he thought there was definite proof that there were also cases arising in non-rheumatic patients from fright only. Fright would supply a cause for the phenomena noticed in the heart. The first thing that followed on fright was pallor—an inhibition of the heart, with local contraction of the arterioles; after that there was a violent reaction and overaction of the heart, such as might be quite enough to cause injury to the valves. He wished to emphasize two different classes of change found in the choreic heart, viz., 1, those due to rheumatism; 2, a smaller group producing a quite different murmur, sometimes even an aortic diastolic murmur, which was transitory.

Dr. Sturges said he was sorry to see the pan-rheumatic

theory of chorea gaining ground. He thought there was a real relation between chorea and rheumatism, but that there was a tendency to exaggerate this relationship. Dr. Herringham had only been able to trace a direct and immediate connection between rheumatism and chorea in four cases out of eighty, and it was often necessary to seek far in order to find the rheumatic element. He contrasted this with fright, the chorea following which came on usually without an interval. Great divergence of opinion existed abroad. In Germany rheumatism was regarded as a trivial element in chorea, whereas the French thought chorea was a mere manifestation of rheumatism. Osler, in the United States, had put together many cases, and found practically no rheumatic proclivity at all. Dr. Sturges observed that the joint pains in connection with chorea were sometimes rheumatic and sometimes not, and he felt there must be some deeper relation between chorea and the joint affection. He urged the importance of treating chorea during the first (emotional) stage, before movement had commenced.

Dr. Barnes alluded to the relationship existing between chorea and pregnancy, and narrated a case where a child had chorea and was cured, but becoming pregnant in later years the chorea returned with increased severity. Chorea, if evoked by pregnancy, often tended to insanity.

Dr. Stephen Mackenzie thought the evidence had become increasingly strong that rheumatism played a great part in the production of chorea. He admitted the gravity of chorea when occurring in pregnancy, but thought some other factor than gestation must be at work.

Dr. Robert J. Lee regarded chorea as a symptom rather than a disease. Though it might coexist with rheumatism, there was no evidence to show that the two bore to each other any relation of cause and effect. He did not think pregnancy could be looked on as a cause of chorea, for the latter occurred so rarely as a complication.

Dr. Herringham, in replying, said he had restricted his inquiries to arthritis because the evidence of other more equivocal data would be rejected by the sceptical. He could only look on rheumatism as a collection of symptoms, as indeed all diseases were.

Dr. Garrod, in replying, remarked that a good deal of the discussion had turned upon what was really meant by rheumatism. He himself regarded it as a general disease, of which arthritis was but one manifestation.

The prolonged discussions on university education in London, and on the question of university degrees for London medical students, have not been wholly without fruit. It is probably partly due to them that the London University has condescended to somewhat modify its iron regulations and take a few steps toward popularizing its degrees. The infrequency with which the several examinations were held was long regarded as a hardship to students. Being held only annually, either the postponement of, or rejection at, an examination necessarily meant the loss of a year to a student. During the last few years the earlier examinations for the medical degrees have been held half-yearly, and last year it was intimated that the final examination for the degree of Bachelor of Medicine would in future be held twice a year also. It is now announced that this change will be brought into effect at once, which will no doubt be welcomed by many aspirants for the degree.

The Colleges of Physicians and Surgeons have not as yet completed their building project on the Embankment. The Examination Hall has been erected, it is true, and is in use, but the remaining buildings are still unfinished. A legal difficulty bars the way at present, for an injunction has been obtained against the colleges restraining them from proceeding further with the buildings, on the ground of interference with the light of the adjoining houses. The authorities of the two colleges are conferring about the matter, and it is hoped some method of carrying out the scheme—possibly somewhat modified—may be devised.

The weather here is often abused, and not without reason. That of last year was certainly exceptionally bad. It is, therefore, gratifying to find that the public health did not apparently suffer in consequence, for during 1888 the death-rate per 1,000 persons living in London fell to 18.5. During the years 1881–87, inclusive, it averaged 20.4 per 1,000 annually, which compares favorably with the death-rate of any other large city on the face of the globe, but the rate for last year was phenomenally low.

OUR PARIS LETTER.

(From our Special Correspondent.)

SOME INTERESTING POINTS ON STROPHANTHUS—AN INDIGESTIBLE SPOON AND LAPAROTOMY.

PARIS, January 18, 1889.

AT the meeting of the Academy of Medicine of last week, Dr. Bucquoy read a note on the action of strophanthus, or rather the two species of strophanthus, the one from the west, the other from the east of tropical Africa, both of which have an identical action and are very favorable in diseases of the heart when they are appropriately employed. He prefers the employment of the plant to that of strophanthine, the history of which, even the chemical, is still but little known. Dr. Dujardin-Beaumetz accepted the greater part of the conclusions of Dr. Bucquoy, and pointed out the remarkable diuretic action of this medicament. In albuminous nephritis Dr. Bucquoy did not find it useful. Dr. Dujardin-Beaumetz, on the contrary, sometimes found it beneficial. This depends on the conditions in which is produced this albuminous nephritis. In cases of renal insufficiency Dr. Dujardin-Beaumetz has obtained, with strophanthus and sparteine, excellent results, but in acute affections of the kidneys it is evidently contraindicated. In cases of sclerosis strophanthus often produces effects superior to those of digitalis. Its only inconvenience is that it produces diarrhœa by its prolonged use; hæmaturia is an absolutely exceptional occurrence. All depends on the state of the myocardium with regard to the result. Of all the preparations of strophanthus Dr. Dujardin-Beaumetz prefers the tincture in the proportion of one-fifth, of which he employs five or six drops morning and evening. He has tried, as a substitute for strophanthus, the oleander, which he administers in the form of extract, in doses of from ten to twenty centigrammes. The effects are absolutely analogous to those of strophanthus, but are less constant. Dr. Dujardin-Beaumetz adds that it is necessary to make new researches on the active principle of the oleander (oleandrine), which is as yet not well known. Professor Germain Sée then took up the subject at the following meeting, and spoke not only of strophanthus, but of cardiac medicaments in general, and also of cardiac affections, which, he said, may permit patients to live a very long time, even without functional troubles. A great number of the diseases of the heart produce no functional trouble whatever, and are discovered only on auscultation. M. Sée prefers alkaloids to extracts, and the different parts of the plants in their entirety. It is said that digitaline is not worth digitalis, but M. Sée thinks it preferable to all the preparations of this plant. Cafeine has become a cardiac remedy of the first order, as it is a marvellous diuretic—diuresis is an effect necessary to obtain in all cases of asystolie. Cafeine should not be confounded with coffee. Cafeine is found in a great number of other substances. It is now very much employed, particularly since it has been rendered soluble, under the form of the benzoate or the salicylate of cafeine. Theine presents a complete analogy with cafeine, and probably it is sold under the name of cafeine in certain pharmacies. Theobromine, taken from chocolate, also renders great service in cardiac affections. M. Sée then drew a comparison between the action of strophanthine and that of other cardiac medicaments. Cardiac affections, he said, form one of the most important chapters of pathology. A cardiac drug should have an elective action on one of

the elements of the heart. There are three symptoms which are to be combated, viz., dyspnœa, which is the most important phenomenon, compensatory hypertrophy of the heart, and dropsies. The best of all the medicaments for these conditions is the iodide of potassium, which, however, has one defect, and that is in not being diuretic. It is an antidyspnœic and a hyperæmiant of the first order. Among the toni-cardiac medicaments are digitalis, convallamarine, the salts of potash, sparteine, and strophanthus. Among diuretics the best is calomel, then come cafeine and strophanthus. Of these diuretics some act on the general pressure, while the others act directly on the kidneys, such as strophanthus, which produces a "strophanthic nephritis," but here the heart has nothing to do with it. Cafeine likewise does not act on the heart—it is purely a renal medicament. The effect produced must therefore be attributed to the diminution of pressure. For this purpose it will suffice to give the medicament which will best diminish the pressure, viz., chloral. M. Sée has promised to continue the subject at the next meeting of the Academy, when other members who have already signified their intention of doing so will likewise take part in the debate.

A case recalling that of "l'homme à la fourchette," which some years ago had procured for M. Labbé, the well-known surgeon, a certain degree of notoriety, has recently been brought to the notice of the Academy of Medicine by Dr. Le Dentu, who, in the month of November last, operated on a young man, aged twenty-one years, by performing gastrotomy, followed by laparotomy, for the removal of a wooden spoon, twenty-seven centimetres long, which the man had swallowed unintentionally while in the act of imitating jugglers who pretend to swallow swords. This act does not seem to have disconcerted him much, as very soon after he dined as usual without experienceing the least inconvenience. In the evening he went to bed as usual, but about two in the morning he suffered from severe pains and a sense of tearing in the region of the stomach. It was in this state that he walked to the hospital, and was admitted in Dr. Le Dentu's ward, where he was received by two internes who distinctly felt the foreign body about two fingers' wide above the umbilicus; but at the regular visit a few hours after it was not possible to ascertain the position it then occupied. The abdomen was firmly contracted to its full extent. The operation of gastrotomy was nevertheless decided upon for the next day. The patient having been put under chloroform, the stomach was brought to view by an opening through the abdominal wall, and an incision of four centimetres was made into the organ. The index-finger was then introduced into the cavity of the stomach, but no foreign body was found. An exploration was made through the wound in the hypochondrium, and the spoon was found vertically placed in the pelvis, one of the extremities was applied to the bladder, and the other lay behind the linea alba and reached three or four centimetres above the umbilicus. Dr. Le Dentu then incised the linea alba to the extent of from nine to ten inches, and removed the spoon without much difficulty. The most minute examination could not lead to the discovery of the part of the stomach which was perforated by the spoon. The patient is now quite well.

THE USE OF DRY CUPS IN DIAGNOSIS AND THERAPEUTICS.

To the Editor of The Medical Record.

Sir: Dr. George White, of Chicago, has communicated a very interesting and practical paper to The Medical Record of January 26, 1889, on "Cupping Glasses as Diagnostic and Therapeutic Means." If it be true, as the doctor's experience leads him to believe, that "the use of these little instruments has fallen into decay," then I think there is need of a resurrection. A paper might be written on the lost arts of medicine, and we are too much disposed, in seizing the valuable new remedies, to neglect those results of careful clinical experience which descended from therapeutists who in some respects were better than those of our present time. All that modern investigation has done in some instances is to show us the scientific reasons for the effects of older experimental methods. The modern antiseptic discoveries are a marked illustration of this, since a large proportion of the medicines used in all time has been of an antiseptic character. In later years the microbe has been dragged from its obscurity and the reason explained why germicides are so valuable in the relief and prevention of disease. I think that in the presence of the old and the new we should occupy the same impartial attitude to each, and hold fast that which is good. I have always found dry cups of great value in renal disease, pulmonary congestions, local rheumatisms, and kindred affections. When an interne at Bellevue I was very much struck by the effect which they exerted on a patient whom I observed while passing through one of the wards, and who was sitting up in bed, bent forward in the effort to relieve a very severe pulmonary congestion. The situation was critical, but by covering the posterior thoracic wall with cups the dyspnœa was soon relieved. Probably others have thought of the use of these agents for diagnosis in renal diseases, but I do not know of any articles which refer to this subject except Dr. White's and my own. In a paper which I read on the "Treatment of Bright's Disease" before the Section on Materia Medica and Therapeutics of the New York Academy of Medicine, December 15, 1886, the following reference is made to the use of dry cups:[1]

"Dry cupping to the loins relieves renal congestion and favors diuresis. By this temporary abstraction of blood into the subcutaneous capillaries a diminished pressure is produced in the lumbar arteries, which supply the integuments of the loins, and this diverts a certain amount of blood from the renal arteries. The object of the cupping is to draw the blood into the capillaries, in order that it may be taken up and removed by the veins. The cups should be removed as soon as filled, and reapplied. No cups are better for the application of this remedy than the ordinary tumbler, which is always at hand. A good method of applying these is to dampen the bottom of the glass, so that the piece of loose dry cotton which is to occupy the bottom of the glass does not fall out when the cup is used. The skin is to be moistened with warm water, and the glass applied instantly after the cotton is lighted, when an excellent vacuum is produced, and the integument rises into the glass. The cupping glass with rubber bulb is also a convenient instrument for dry cupping. It has seemed to me that when the blood under the cups remained purple and stagnant after their removal, this indicated marked renal congestion, and that the reddened integument more quickly recovered its color in proportion as those symptoms disappeared which implied the presence of an excessive amount of blood in the kidney."

This subject is worthy of further study. Dry cups are valuable as affording an external remedy which is prompt and efficient, and often a most desirable substitute for medicines. Probably they will develop uses in other branches of diagnosis if the mechanism of their effects is carefully observed.

F. A. Burrall, M.D.

48 West Seventeenth Street, New York.

SCHOOL FOR MALE NURSES.

To the Editor of The Medical Record.

Sir: There is a young man here who has had some experience in nursing, and who desires to become an experienced nurse. He learned somewhere that there was a hospital in New York City that trained young men in that profession free of charge, and came to me for in-

[1] This paper was published in the Therapeutical Gazette of February 15, 1887.

formation. I promised to write and find out what I could, and so appeal to you. By giving me what information you can you will confer a favor upon me, as well as the young man mentioned.

Yours very truly,

BEN. M. LEWIS,
Secretary Y. M. C. A.

YOUNG MEN'S CHRISTIAN ASSOCIATION,
WATERTOWN, N. Y., January 24, 1889.

[The Bellevue Training School for Male Nurses receives young men who pass the qualifying examination, and trains them in Bellevue Hospital. It gives them board and a small sum weekly, and graduates them in two years.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 27 to February 2, 1889.

LORING, L. Y., Major and Surgeon. Granted leave of absence for one month on Surgeon's certificate of disability. Par. 1, S. O. 6, Headquarters Department of Arizona, Los Angeles, Cal., January 18, 1889.

PRICE, CURTIS E., Captain and Assistant Surgeon. Leave of absence granted in S. O. No. 257, A. G. O., November 3, 1888, is extended two months. Par. 1, S. O. 21, A. G. O., January 25, 1889.

KILBOURNE, HENRY S., Captain and Assistant Surgeon. Will accompany Battery E, First Artillery, changing station from Vancouver Barracks to Presidio, San Francisco, Cal., as Medical Officer, and upon completion of this duty will report to the Commanding General, Division of the Pacific, for further orders. Par. 2, S. O. 6, Headquarters Department of Colorado, Vancouver Barracks, January 22, 1889.

BURTON, HENRY G., Captain and Assistant Surgeon. Leave of absence granted on Surgeon's certificate of disability, in S. O. No. 19, January 24, 1888, from this office, by direction of the Secretary of War, is extended six months on Surgeon's certificate of disability. Par. 8, S. O. 22, A. G. O., Washington, January 26, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending February 2, 1889.

SCOTT, H. B., Passed Assistant Surgeon. Detached from Naval Hospital, Mare Island, Cal., and granted one year's sick leave.

RHINANTHIN.—A glucosidal substance, similar to digitalin, obtained by Dr. Phipson from the common snapdragon (*Antirrhinum majus*), has been identified by him with rhinanthin, a glucoside extracted twenty years ago by Ludwig from the seeds of rhinanthus hirsutus and R. crista-galli. Dr. Phipson describes rhinanthin as occurring rather plentifully in the leaves and stalks of the snapdragon, from which it can be separated by macerating the plant in cold water for a few days, filtering, and treating the filtrate with a small quantity of lead subacetate, again filtering and removing any excess of lead, and evaporating the liquid to a syrup. After a few days rhinanthin separates in brilliant transparent, colorless rhombic crystals, having a peculiar sweetish-acrid taste, and very soluble in water and in alcohol. A clear, colorless aqueous solution of rhinanthin, heated in a test-tube with a few drops of hydrochloric acid, turns gradually brown, and just after boiling becomes dark and opaque, through the breaking up of the glucoside; a copious reddish-brown precipitate of rhinanthogen is formed, and glucose can be detected in the liquor. This reaction is said to be a very delicate test for the presence of rhinanthin. —*Pharmaceutical Journal.*

Cholera	0	0

FOR THE INFORMATION OF PERSONS DESIRING TO ENTER THE MEDICAL CORPS OF THE UNITED STATES NAVY.—A candidate for examination and appointment in the Medical Corps of the Navy must be between twenty-one and twenty-six years of age, and must apply to the Honorable Secretary of the Navy for permission to appear before the Naval Medical Examining Board. The application must be in the handwriting of the applicant, stating age and place of birth, also the place and State of which he is a permanent resident; and must be accompanied by letters or certificates from persons of repute, testifying, from personal knowledge, to his good habits and moral character, and that he is a citizen of the United States.

Form of Application.

———— ——,

———— —, 188—.

TO THE HONORABLE SECRETARY OF THE NAVY,
Navy Department, Washington, D. C.:

SIR: I request permission to be examined for an appointment as Assistant Surgeon in the United States Navy.

I was born at ————, and was ———— years of age on the ———— day of ————, 188—, and am a citizen of the United States, residing in ————, county of ————, in the State of ————.

I enclose herewith certificates as to moral character, habits, and citizenship.

Very respectfully,

———— ————

If, in reply to the above, the candidate receive a permit, he will notify the President of the Board of the fact, and request him to appoint a time for his examination. Candidates will be expected to present to the Board testimonials of educational and professional fitness. The Board is required, under oath, to report on the physical, mental, moral, and professional qualifications of the candidate; so that the examinations are necessarily rigid and comprehensive, though simple and practical, and not beyond the attainments of any well-educated physician. A successful candidate, upon the completion of his examination, will be notified by the President of the Board that he has been found qualified. An applicant found "not qualified" may be allowed a second examination after one year, but not a third. No allowance will be made for the expenses of persons undergoing examination, which, if uninterrupted, is usually completed within a week. Appointments will be made as vacancies occur, and in the order of merit reported by the Board, but a qualified candidate, not appointed within a year, must be re-examined. The officers of the Medical Staff of the Navy are as follows: Medical Directors, Medical Inspectors, Surgeons, Passed Assistant Surgeons, and Assistant Surgeons. Vacancies in these grades (by death, or retirement at the age of sixty-two years) are filled in the order of seniority, and

for each step of promotion a physical and professional examination is required by law. The pay of an Assistant Surgeon in the Navy is $1,000 per annum "on leave or waiting orders," $1,400 "on shore duty," $1,700 "at sea," and, when at sea, one ration at thirty cents per diem in addition. Eight cents a mile is the allowance when travelling under orders.

Order of Examination.

1. Physical. 2. Written. 3. Oral. 4. Clinical. 5. Practical.

The physical examination will be very thorough, and the candidate will be required to certify, under oath, that he is free from any mental, physical, or constitutional defects, hereditary taint, or disability of any kind that would be liable to interfere with the efficient performance of duty.

Written examination.—The candidate will be required to address a letter to the Board of Examiners, stating concisely: 1. The date and place of his birth; the school, institution, or college at which he received his general education; the several branches studied, including his knowledge of general literature, and of the ancient and modern languages; the exact title of the medical school or schools at which he received instruction, and, if an Alumnus, the date of his graduation; the name and place of residence of his preceptor, and the time when he commenced the study of medicine; also, the title of the text-books studied or read on chemistry, anatomy, physiology, history, materia medica, pharmacy, therapeutics, theory and practice of medicine, principles and practice of surgery, minor surgery or mechanical therapeutics, medical jurisprudence, toxicology, obstetrics, hygiene, biology, and physics. 2. The opportunities he has had of engaging in the practice of medicine, surgery, and obstetrics, or of receiving clinical instruction; or whether he has or has not been a resident physician or interne in a civil or military hospital. 3. The number of subjects or parts of subjects he has dissected; what opportunity he has had to become familiar with minor surgery and bandaging, chemical and pharmaceutical manipulations, and the physical properties of drugs. The candidate will append to this letter his name in full, post-office address, and his local address at the date of the examination.

A thesis or short essay must next be written (without reference to notes or books) upon some professional or scientific subject indicated by the Board. Written answers will then be required to twelve or more questions, propounded by the Board, on the following subjects: Anatomy, Histology, Physiology, Surgery, Theory and Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Hygiene, Medical Jurisprudence, Toxicology, and Physics.

Oral examination.—The candidate will be examined orally upon his literary and scientific acquirements, including general history, natural science, and English literature, and professionally upon Anatomy (general, special, and surgical), Histology, Physiology, Theory and Practice of Medicine, Principles and Practice of Surgery, Chemistry, Legal Medicine, Toxicology, Materia Medica, Therapeutics, Pharmacy, Obstetrics and Diseases of Women and Children, Hygiene, Microscopy, and Physics. Candidates possessing special knowledge of the higher Mathematics, Astronomy, Geology, Botany, Zoology, Literature, Art and Ancient and Modern Languages, will be given full credit for their proficiency.

The clinical examination of patients will be made by the candidate at a Naval Hospital, and will include the use of the Microscope, Thermometer, Laryngoscope, Ophthalmoscope and other aids to physical diagnosis; after which he will be required to submit a written clinical report on one or more medical or surgical cases.

The practical examination will comprise surgical operation on the cadaver, the application of splints, bandages, and surgical dressings, the use of the microscope (for clinical purposes, and the recognition of pathologcal or other specimens), and chemical and pharmaceutical manipulations. A candidate may withdraw at any period of the examination, with the consent of the Board, and may at a future time present himself for re-examination. The Board may conclude the examination—written, oral, or practical—at any time, and may deviate from this general plan in such manner as it may deem best to insure the interests of the naval service. WILLIAM C. WHITNEY, *Secretary of the Navy.*

MATERNAL IMPRESSIONS.—Dr. T. B. Nichols, of Plattsburg, N. Y., writes: "In THE MEDICAL RECORD of January 12, 1889, page 43, Dr. R. Gross, of Eureka, Cal., cites two cases that came under his observation which are clearly set forth, and which have left him fully 'convinced that in certain cases, in nervous women, shocks may and do leave an impress on the fœtus *in utero*.' Now, though no one can doubt Dr. Gross' honesty, etc., in his belief, as represented in the article above referred to, another person whose mind is differently constituted might naturally inquire, after reading his paper, if the hare-lip and the blistered surface as seen in Dr. Gross' particular cases are really due to maternal impressions, why may not *all* the monstrosities and deformities that are found among or on the newly born children, in the various walks of life, be due to maternal impressions? Every practitioner of large experience in midwifery must have seen large numbers of cases in almost every conceivable variety of deformity that were not traceable to any disturbance of the mother's mental equilibrium. Assuming, then, that the negative is the *general rule*, will someone please rise and give us the *exceptions?*"

ANTISEPTIC SURGERY AT THE HOSPITAL DE LA SALPÊTRIÈRE; USE OF BOILING WATER.—M. Terrillon (Paris) insists particularly upon the value of disinfection of instruments by boiling water. Pasteur's experiments first, and afterward Roux's, have demonstrated that water at 100° C. destroys all pathogenic microbes. It is true that the spores resist this temperature, but they lose the faculty of developing rapidly, and, besides, a second immersion in boiling water some days afterward will kill the microbes to which the germs have given origin. Lastly, as a matter of fact, all the surgeons who have made use of this means of disinfection have had marvellous results. After every operation the cleansed instruments should be plunged for ten minutes into boiling water, and before the next operation, they should be again immersed for ten minutes. Water at 100° C. serves also for the disinfection of silk. After ten minutes' boiling it is placed in bottles filled with Van Swieten's solution or carbolic lotion. At the moment of use it is once again plunged into boiling water. M. Terrillon covers the points of suture with a layer of iodol or iodoform ointment, and strongly recommends the practice.—*Annals of Surgery.*

TAXING PHYSICIANS.—The Salt Lake City Council has recently ordered that all physicians practising in that city shall pay a license tax. The Salt Lake Medical Society has protested strongly against the imposition of the tax, but thus far apparently without success.

A CHEMICAL BALLET.—At a banquet which was given at the conclusion of the German Congress of Naturalists and Physicians at Cologne, Dr. Hoffman alluded to the difficulty experienced by students in understanding the constitution of organic compounds, and suggested an original method of fixing these in their minds. The audience were then treated to a ballet, in which the *danseuses* were dressed in different colors to represent the various atoms. At his command, these colored female atoms grouped themselves in various fashions to show the chemical constitution of particular compounds and their reactions. The composition of benzol and the formation of aniline and its derivatives were particularly applauded. The ballet wound up by a representation of the formula of roburite, the new explosive, the *finale* being a formidable explosion.—*Medical Press.*

THE TREATMENT OF FISTULA IN ANO.

BY CHARLES B. KELSEY, M.D.,

NEW YORK.

THE general idea of the operation of cutting a fistula in ano is a very simple one. It is that a director should be introduced into the external orifice, brought out into the rectum through the internal opening, or at a point where its end approaches most nearly to the mucous membrane, then bent and brought out of the anus, and that the tissues upon it should be cut.

This is the idea conveyed to the student by his lectures, and to the practitioner by his text-books on general surgery, and in many, perhaps the majority, of cases, this simple procedure will be curative; for many fistulæ are straight tracks running not very deeply into the tissues, and it is to them, and to them only, that the operation applies. But no practitioner will cut many fistulæ in this off-hand, routine way before meeting with a case in which such an operation will either prove a signal failure or will result in irreparable injury to the parts.

FIG. 1.

Perhaps the first lesson taught by an unexpected failure in effecting a cure by this operation is that a fistulous track is something to be followed by a careful dissection, and not a thing to be laid open by a single sweep of the knife along a director which has, by more or less force, been entered at one opening and made to pass out at the other; for by this course not only is the track often left in great part undivided, but the director is forced into healthy tissue and parts are needlessly sacrificed.

Instead of this, the track should be followed step by step from its external opening along its whole course; and to do this the director need only be introduced a short distance at a time. By thus following carefully the course of the fistula no unnecessary sacrifice is made of adjacent healthy tissue, and side-tracks or diverticula are recognized as they are met. This is much easier than to pick them out in the bottom of an extensive bleeding and irregular wound.

A word about the director. The one ordinarily used is too blunt at the end for fine work. It should be of steel, delicately made, and probe pointed (Fig. 1); silver is too flexible for ordinary work. These have been made for me in three sizes by Tiemann.

With regard to side-tracks, or branching diverticula, the rule is that all such should be dissected up exactly as the main track should be; but to this there are very important exceptions. The rule may perhaps be modified in this way. As many tracks should be divided as can be done without the risk of incontinence of fæces in either sex, or of destruction of the perineum in women, or of too great injury for the reparative powers of the patient.

As a rule, both the sphincters in either sex may be divided once in the median line without danger of incontinence. It is better, however, to divide as little as possible. The inner should be left intact, if possible; the division should be straight across the muscular fibre and not slanting; and a double division of one, and especially of both sphincters, should not be resorted to as a primary operation. In women and phthisical patients there is more risk than in men otherwise healthy.

In these modifications of the rule of complete division cases of tracks running upward along the bowel are not included, for these should be divided as are those nearer the anus.

Here the supposed danger of hemorrhage often stops the operator with his work half completed; and one of these tracks will often heal spontaneously after the opening of the lower one into which it empties. But it is not safe to trust to this chance. These upward branches are of two distinct kinds. In one the track runs directly beneath the mucous membrane, and may be so found with the director; and in this there is little danger of hemorrhage in its division, for the blood-vessels are all beneath it. In the other variety the track runs deeper in the wall of the gut, under the muscular layers, perhaps even away from the rectal wall into the perirectal tissues. In such cases there is great danger of hemorrhage, and the

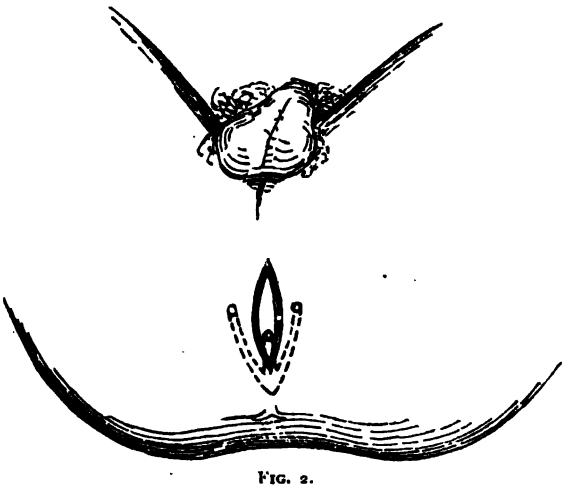

FIG. 2.

division may be more safely done with the elastic ligature or the enterotome.

The exceptions to this rule of complete division will be found in three classes of cases—those of the horse-shoe variety, the recto-labial variety, and the old cases of extensive disease, where the whole anal and perineal regions are riddled with openings. In these cases all the ingenuity the operator possesses will be demanded to effect a cure without resulting incontinence.

Horse-shoe fistula has been defined differently by different writers. In a typical case it is a form of fistula in which there are one or more external openings on each side of the anus and an inner opening in the rectum in the median line behind. It is shown in Fig. 2, after Goodsall.[1] But a horse-shoe fistula may have only one external opening and yet the abscess which has caused it may almost entirely surround the gut. Nor need the internal orifice be in the median line, either behind or in front. The name applies better to the shape of the abscess which has resulted in fistula than to the location of the openings. In this form of disease the pus in its burrowing has extended from one side of the gut to the other, and the resulting fistula may be complete, incom-

[1] British Medical Journal, 1888.

plete, or of the blind internal variety. The internal opening may be at any point, and the external may be on the opposite side of the body from it (Fig. 3).

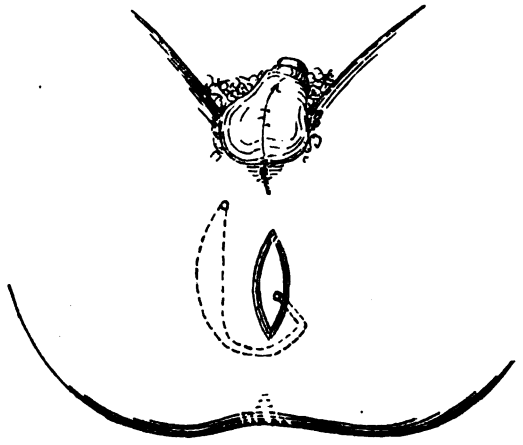

FIG. 3.

In these cases I think it will generally be observed that the openings do not lead into distinct fistulous tracks of any great extent, but rather into one abscess cavity of considerable size.

It is evident that in operating upon such cases as these there is a chance for much skill in effecting a cure at one operation, and still preserving the sphincteric power. And I may say that a patient who has been left with incontinence of fæces after this operation is apt to be very unforgiving, especially when it happens to be a lady who has been rendered loathsome to herself, afraid to trust herself in society, and doomed to the constant wearing of a napkin. I have seen several such, and by means to be referred to have relieved some, but from the ill-fortune

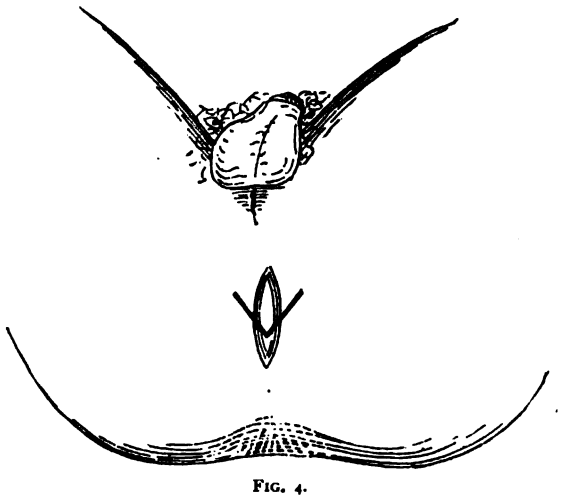

FIG. 4.

of others I have come to warn my own patients that incontinence may possibly result, when I see any reason to anticipate such a conclusion.

Taking now a case of horse-shoe fistula, such as is shown in Fig. 2. The ordinary operation would consist in two complete divisions of the sphincters on opposite sides (Fig. 4), probably resulting in incontinence. The correct method, as is shown by Goodsall, consists in one complete posterior division, and then the opening of the lateral tracks into this posterior cut, as shown in Fig. 5.

This principle may be made to cover nearly all of this class of cases. Where several external openings are grouped around the anus they may all be connected by one incision, and from this incision a probe may be passed through the internal opening, and this, too, divided with the sphincter.

In case the external opening be at a considerable distance from the anus, and on the opposite side of the body from the internal, as shown in Fig. 3—drawn from a case of my own—the method is essentially the same, the thing to be avoided being a slanting cut through the rectum and healthy tissue. By following the ordinary rule in such a case—passing a director into one opening and out of the other and cutting upon it—all but a small portion of the lower end of the bowel would be completely severed by a deep incision. Fig. 6 shows the cuts that were made by which a cure was effected without incontinence.

It may easily occur that in a complicated case it is found impossible to divide all of the tracks without a double or even triple division of the muscles. In such cases the safer practice is to do such an operation as has been indicated upon all the tracks that can be included

FIG. 5.

in a single division of the muscle, and to trust to other means of cure for the balance, at least till the first wound has healed.

The most reliable of these other means is the injection of strong tincture of iodine into the uncut tracks. Many of them will have been thoroughly drained by the first incisions and will heal with the additional stimulus of this treatment. They may even be thoroughly cauterized with fused nitrate of silver at the time of the operation.

The second class of cases in which it may be unjustifiable to divide all the tracks at the primary operation is that of the recto-labial fistulæ.

This form of disease is in most cases due to inflammation of one or both vulvo-vaginal glands or their ducts, leading to suppuration and the final escape of pus, both on the labia and within the rectum. There may be numerous external and internal openings. In the case shown in Fig. 7, recently operated upon in consultation with Dr. Kennedy, there was a labial opening on each side. The right track had opened on the anterior wall of the rectum in two places, the left in one, and the right

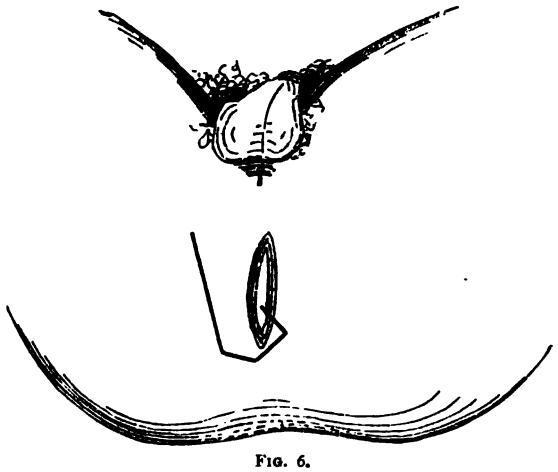

FIG. 6.

and left tracks communicated by a submucous track n the rectum. In such a case the division of both tracks would result in a complete double division of the whole perineum, as well as of the external sphincter.

The cuts made at the primary operation are shown in Fig. 8.

A probe was first passed through the track on the right side, from the external opening down to the verge of the anus, its end cut down upon and brought out through the skin of the perineum at the point B. From this point it

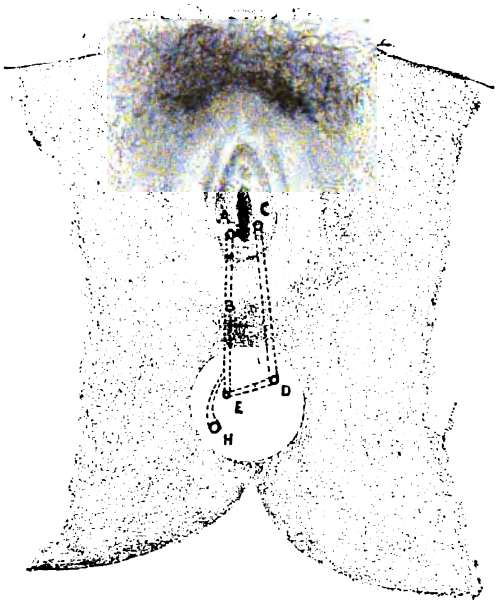

FIG. 7.

was carried along the fistula to the internal opening on the same side, and this part of the track divided with the sphincter. The director was then again passed from the opening D to the first cut, and the cross-track divided. Finally, all of the submucous tracks were slit up, and the track on the left side, from its internal opening as far as was possible, without complete division of the sphincter at that point. Setons were then passed along what remained of the original tracks and tied. The result was not a perfect cure in the first instance, only the rectal

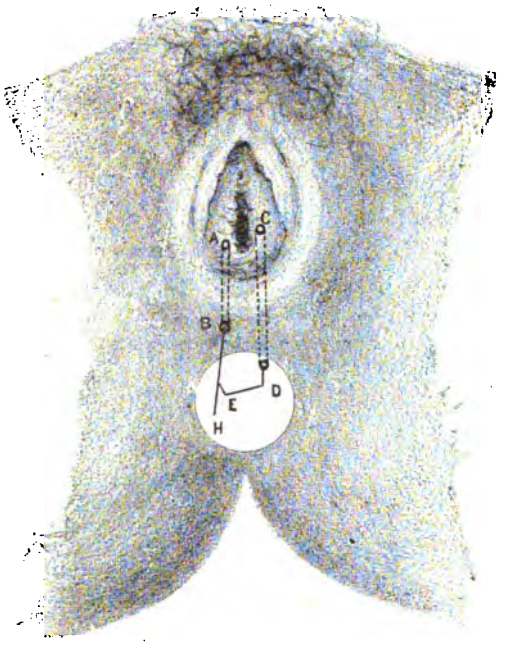

FIG. 8.

tracks being closed, but by the primary operation the subsequent treatment of the two straight perineal tracks was rendered much simpler.

Dr. I. E. Taylor [1] has made a careful study of this rare form of disease, and describes two different methods of operating, both, however, with the elastic ligature. The first is that recommended by Barton, in which a ligature is passed from the labial to the rectal orifice and brought out at the anus; an eyed probe is then passed from the labial orifice down along the perineum till it reaches just outside of the sphincter ani low down, its point is cut down upon, and the labial end of the ligature is drawn through this artificial opening and the ends fastened. The other operation is the same, except that the stages are reversed, the artificial opening being first made and the ligature passed from this through the rectal opening and brought out at the anus. In this way the track through the perineum is not divided, but is left to close with appropriate stimulating applications.

The blind internal fistula is the one which, more than all others, leads to mistakes in diagnosis. The absence of any external orifice misleads the superficial examiner at the beginning, and the failure to make a thorough examination completes the error.

There are two signs of this condition which will in every case lead to a correct diagnosis. The one is the discovery of the internal orifice, the other, the induration which invariably attends a track of any size. Again, there is something significant in the history, and I have learned by experience, when a patient gives all the usual symptoms of fissure, and yet has no fissure, to examine, under ether, for a blind internal fistula. I say examine *under ether* advisedly, for a complete examination without ether and a large-bladed speculum is an impossibility. Often a careful search over the lower three inches of mucous membrane will reveal a small ulcerated opening, and a probe passed into this will run for an inch or so under the mucous membrane. In other cases the finger will first detect an indurated spot or track, and a careful examination of this will show the opening of the fistula. In the submucous variety there is little or no induration, while in the submuscular the induration is likely to be distinct.

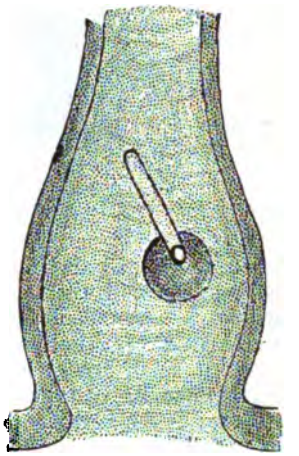

FIG. 9.

This variety of fistula is not, in my experience, very uncommon. It may arise from an abscess which has pointed into the rectum and not on the skin, or it may be due to an inflammatory or ulcerative process commencing in the rectal wall and resulting in perforation, such as tubercular disease. It is sometimes caused by inflammation of an internal hæmorrhoid, and I have seen several cases directly and unmistakably due to the injection of carbolic acid into hæmorrhoids.

The acid not infrequently sets up a circumscribed inflammation, which results in a small abscess breaking on the mucous surface, and burrowing under the mucous membrane, if it has been deposited directly under the surface; or under the muscular coat, if it has been more deeply placed. These fistulæ are generally not very extensive, the track being an inch or so long and generally single, unless more than one injection has been followed by the same result. In a feeble patient with phthisis and relaxed fibre I have seen the mucous membrane undermined in almost every direction as a result of a course of treatment with injections of thirty-three per cent. acid; and in a patient of different fibre I have seen a large abscess of the ischio-rectal fossa, with brawny swelling of the buttock, bursting high up in the rectum, follow an injection of the pure acid.

The larger the abscess and the larger the opening into the rectum—it is sometimes so large that the end of the finger will pass into it—the easier the diagnosis. It is only the lesser forms of the disease that are liable to be

[1] Transactions New York State Medical Association, 1885.

overlooked, and yet even the lesser ones may render a patient's life very miserable.

There are two other points in the diagnosis of this affection that may be useful. One is, that the internal orifice when small may sometimes be detected by gentle pressure on the adjacent parts which shall force a drop of clear pus out of it; the other is, that in cases of circumscribed ulcer which refuse to heal under treatment, a blind track leading from the base of the ulcer should always be carefully searched for.

The treatment is simple in theory, but sometimes difficult to carry out. Large abscesses of the superior pelvi rectal space which have opened into the rectum should be treated by the introduction of drainage-tube, and daily washing out with boracic acid solution. Those located in the ischio-rectal fossa should be opened on the skin, thoroughly cleaned out, and treated by drainage and

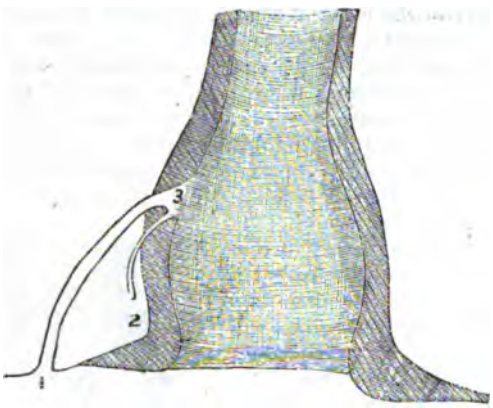

FIG. 10.—Fistula with Double Track. 1, Original incision; 2, secondary track; 3, ulcer remaining.

injections to give the internal opening a chance to close without dividing the tissue between the two openings, which is often considerable. Should this fail the ordinary operation may be done. In the lesser cases of small tracks without abscess cavity the track must be laid open. The rule is to enter a director at the opening into the bowel, bend it so as to follow the track, and then lay the latter open by cutting. When the track runs upward, as in Fig. 9—which, by the way, was a case due to carbolic acid, which attracted considerable attention before the cause of the patient's suffering was discovered—this is not difficult, but when it runs toward the skin, and both opening and track are small, as in Fig. 10, it is a very difficult and uncertain proceeding. Where the induration approaches near enough to the surface to be easily felt, I have in some cases cut directly down upon this through the skin without any director, and have then found no difficulty in passing a director onward through the internal opening. If, however, there is no friendly induration to guide the knife, the track must be carefully dissected out from the internal opening. It is easy under these circumstances to make a false passage with the director, and thus lose the true one, and fail, in spite of free cutting, to cure the case.

In the case pictured in Fig. 10 I found it nearly impossible to follow the track with a bent probe, the opening being a considerable distance from the anus, but it was finally satisfactorily laid open with the curved knife shown in Fig. 11. These are operations requiring patience and care, but with the rectum well exposed, under ether, there need be no difficulty. The knife of my own invention (Fig. 12) is sometimes very useful in these cases.

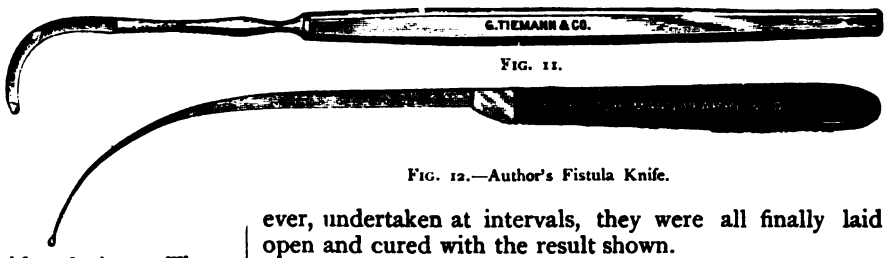

FIG. 11.

FIG. 12.—Author's Fistula Knife.

In fistulæ with very long and deep tracks, or in those with many smaller ones, a cure without an amount of cutting which shall necessarily lead to incontinence may be impossible. Fig. 13 is taken from a case of the latter variety, where the openings and tracks were so numerous, and the patient's general condition so bad, that a cure was for some time despaired of. By several operations, however, undertaken at intervals, they were all finally laid open and cured with the result shown.

In these cases care must be exercised not to overtax the strength of the patient by too much cutting at any one time. The tracks can often be divided into two or three main ones, each with secondary side-tracks, and it is better to attack one main track and its branches at a sitting, leaving the others till the patient has gained strength by change of air and appropriate treatment.

In the cases of a single but very long and deep track it may not be best to divide everything at a single sitting, as, for example, where one opening is high up in the rectum and the other in the middle of the thigh. The question as to how much it is safe to do at one time must depend in great measure upon the strength of the patient; and it is often better to begin at the external opening and follow the fistula up to the buttock at one operation, leaving the remainder for treatment by injections or subsequent cutting.

In these deep tracks a galvano-cautery knife or wire may be better than a bistoury. A very strong knife may easily be broken in such a case as is shown in Fig. 14. The external opening here was over the great trochanter, and the case was very naturally mistaken for hip-joint disease by several operators. The track had been laid open under this impression several times, but never induced to heal. It finally came under the care of Dr. H. M. Lewis, of Brooklyn, who succeeded in passing a probe into the gut, but the knife broke in the callous tissue. An écraseur was next used, with the strongest picture-cord doubled, and this was broken. Finally the ingenious idea occurred to the operator of passing a chain-saw, and by this means

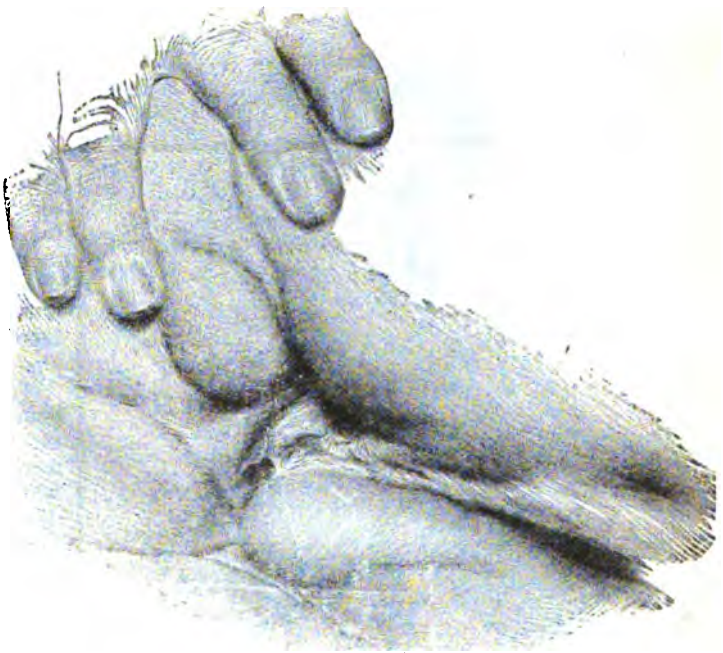

FIG. 13.

the cicatricial tissue was finally divided and the patient cured.

The cause of incontinence after operation for fistula has been the subject of considerable argument, for in some cases a single incision through the external sphincter has been followed by this untoward accident, while in others very extensive and numerous incisions have left the patient still with good control. Smith believes it to be due not

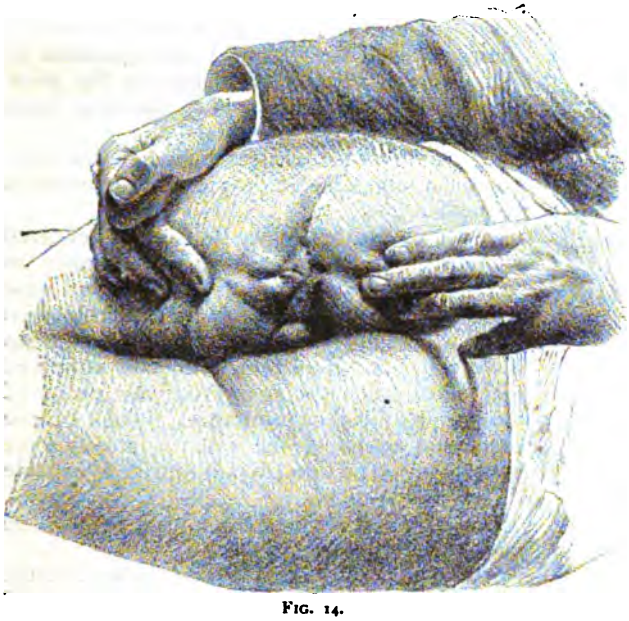

Fig. 14.

so much to the division of the sphincters as to division of the circular muscular fibres of the lower part of the rectum; while Esmarch holds rather to the theory that it is due to division of the nerves supplying the muscle more than to the division of muscular fibres.

In my own mind the explanation lies in the fact of vicious cicatrization, by which the ends of the divided muscles are not brought into apposition in healing. On this supposition it is easy to understand why a single cut may result in loss of muscular power, the ends of the sphincter being separated by an interval of half an inch, and the muscle therefore having no fixed point of support;

Fig. 15.

while in other cases several incisions which have healed properly may still leave the segments of the muscle in shape to act as one undivided circle. The simplest form of the same condition is seen in lacerated perineum in the female. Here a single rent is followed by almost complete incontinence, and although the perineum may be perfectly restored by operation there will be no return of sphincteric power till the cut and separated ends of the muscle are brought into apposition.

The condition is one which entails a greater or lesser degree of misery, depending upon the consistency of the fæces, and the regularity with which they are voided. To a man who has one solid, natural evacuation before going from his house in the morning, there may be no suffering and little annoyance, except what arises from the involuntary escape of wind and the soiling of the person with the natural mucous secretion of the bowel. The fact of inability to control the passage does not necessarily imply that the passages escape in a way to cause annoyance, for when they are of natural consistence and passed with regularity there is generally sufficient warning to allow the patient to seek the closet, which he has learned never to be far away from at a certain hour. The greatest suffering comes in women when the bowels are loose; then there is absolutely no chance to avoid the consequences; a napkin is constantly worn, and the patient soon becomes a confirmed invalid.

If the anus be open and patulous, more or less prolapsus may follow; and this is a fresh cause of tenesmus and discharge, complicating and increasing the original trouble. The train of nervous symptoms following this condition is often in itself serious, and apparently out of proportion to the physical disability.

In the treatment of this condition the operator has an ample field for the exercise of all his ingenuity, for no

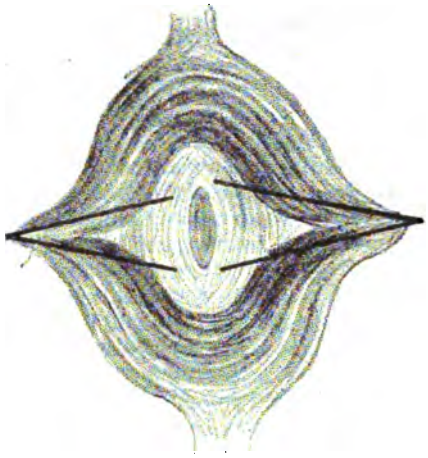

Fig. 16.

BOSTON CITY HOSPITAL. MEDICAL LIBRARY OF THE

two cases will be found exactly alike, and the operations must vary accordingly.

Some will be seen at a glance to be manifestly incurable, such, for example, as the one shown in Fig. 13, where the sphincters have been cut again and again in different directions, till the anus has lost entirely its original shape, and it would be difficult to find any trace of the sphincter by the most careful dissection. Most cases, however, are amenable to operation and relief, and a successful operation brings much sincere gratitude to the operator.

There are two guiding principles in operating. The first is, to find the ends of the sphincter and unite them by suture; the second is applicable where the first is impossible, and consists in producing an artificial tightening and closure of the anus, without much regard to sphincteric action.

The first indication may often be followed out at the time of the original operation for fistula, and is, in fact, done in the operation for immediate closure of the incision by suture of the wound, under antiseptic precautions. In extensive tracks and abscess cavities the operation may fail, but in single deep cuts it often succeeds, and it is always worthy of trial with the object of obtaining direct and immediate union of the ends of the muscle and avoiding possible incontinence.

In cases such as are shown in Figs. 15 and 16 the operation is the same as in lacerated perineum—cutting down upon the ends of the muscle, freshening the edges of the original incision, and bringing them together with wire or catgut sutures.

In a case such as is shown in Fig. 17 the operation is much more complicated. This patient, in spite of all the

cutting which had been done, was still suffering from a blind, internal fistula when he came under my care. In the figure the parts are not at all stretched open. The anus is seen as an irregular circle composed of cicatricial tissue, which held it wide open. The cicatrix extended an inch

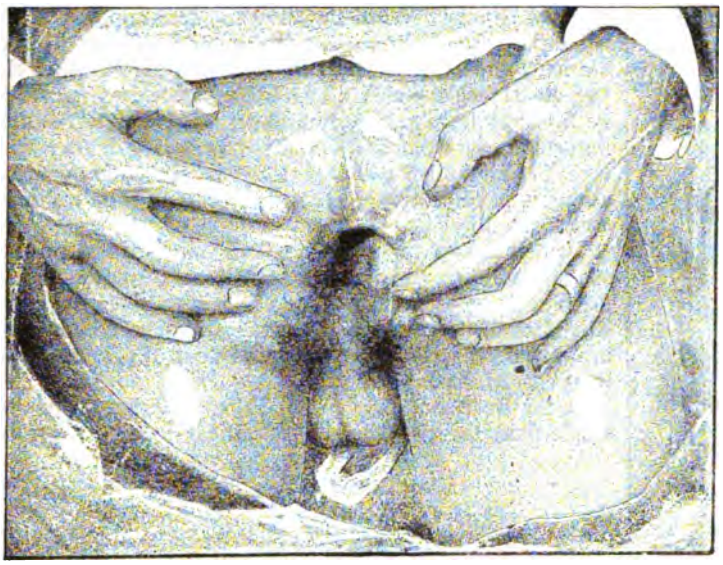

FIG. 17.

and a half into the rectum on all sides, and no mucous membrane was seen till beyond this point. The anus and lower part of the rectum presented an open tube about an inch in diameter, entirely without any power of muscular contraction. At the point where the folds of mucous membrane first appeared there was an opening leading into a deep sinus in the right buttock, and this was opened up, relieving the patient of the pain and purulent discharge from which he suffered.

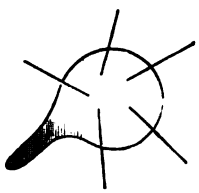

FIG. 18.

Even in this case, with anus and lower part of rectum converted into an open, unyielding tube, the patient did not complain of incontinence, though there could have been no action of either sphincters or levator,

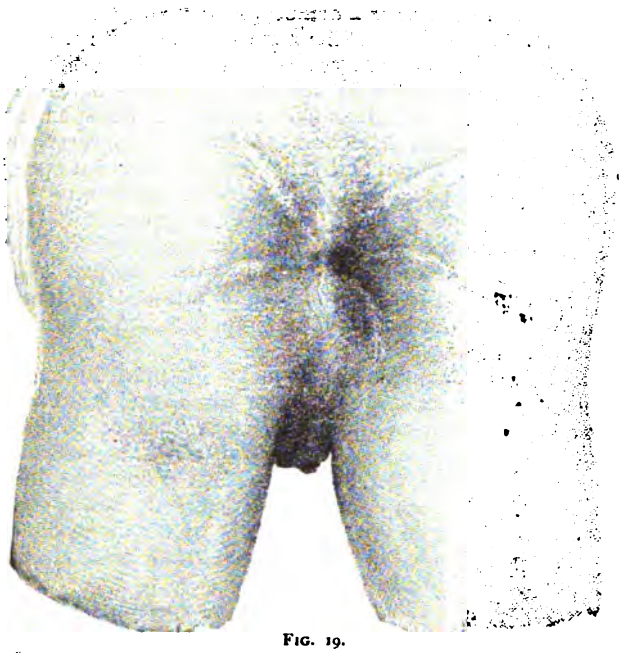

FIG. 19.

and hence no control. He simply had a natural passage every morning, and was never subject to diarrhœa.

In such a case the anus could only be closed by a plastic operation. The plan I proposed was to dissect the mucous membrane loose, draw it down, and stitch it to the skin, after freshening the cicatricial ring of the anus, so as to first give a mucous lining to the parts; then, by a subsequent plastic operation, or perhaps by the cautery-iron, to close the outlet of the canal. But after the fistula was cured, the patient, suffering really no inconvenience, declined further operation. The case proves better than any I have ever seen that loss of sphincteric power is not always attended by any inconvenience.

In the second edition of my work on the rectum I described and figured the other operation to which I have referred for tightening the anus. Fig. 18 shows the cicatrix and the burnings made by the actual cautery for its relief.

Fig. 19 shows the result in tightening the anus, and at the same time, in drawing it to one side of the median line.

In this way the orifice is simply rendered smaller, and the muscles have more chance to close it. The levator ani, the internal, and what remains of the external sphincters, by combined action will compress, and, in a measure, close an orifice which has thus been artificially strictured to an extent sufficient to prevent the escape of fæces under most circumstances, though of true sphincteric action of the external muscle there is very little. The operation, however, is capable of giving great relief.

There is another point which may, perhaps, be touched upon with advantage.

In the great majority of fistulæ there is an internal opening into the rectum, but there are many exceptions to this rule, and these must be taken into consideration in operating. For example, the young operator passes a stiff, blunt director into the external opening and feels for its end in the rectum, but cannot find it. Believing that there must be an internal opening, he probes carefully for a few moments and then begins to use force. After a time the end is felt just outside the wall of the bowel, and is pushed through and brought out at the anus, and the incision is made, but it is easy to see that in only a very small proportion of cases can such an incision follow the fistula. In most cases a false track has been made, and in many the sphincters have been unnecessarily divided.

The rule, I think, should be this: Begin the dissection at the external opening, and follow the track along inch by inch. If it lead into the rectum there will be no difficulty in finding the opening, and then the sphincter may be cut. If it lead away from the rectum there can be no justification for forcing the incision into the rectum. Sometimes it will be found that the track leads close up to the rectal wall, but the exact point of perforation, if there be any, may not be found. In such cases it is better to make an opening into the bowel and divide the sphincter; for where nothing but rectal wall, and perhaps mucous membrane intervenes between the fistula and the cavity of the bowel, a perforation will probably take place after the operation, even if it does not exist at the time.

TREATMENT OF FROST-BITES.—The best remedies for frost-bites, according to M. Ch. Eloy, writing in the *Bulletin Général de Clinique et de Thérapeutique*, are local applications of nitrate of silver, oxide of zinc, iodine, and iodoform. Nitrate of silver may be applied in solution, 3 grains to the ounce, or in ointment, 4½ grains to the ounce. Oxide of zinc is used in an ointment of 75 grains to the ounce of vaseline. Billroth uses an application of 12 grains of metallic iodine to an ounce of vaseline, using sometimes, also, compresses wet with a mixture of one part of cherry-laurel water to three parts of distilled water. Finally, a very useful application is a mixture of 24 grains of iodoform in an ounce of collodion.

THE TREATMENT OF TYPHOID FEVER.[1]

By SIMON BARUCH, M.D.,

ATTENDING PHYSICIAN TO THE MANHATTAN GENERAL HOSPITAL AND THE NEW YORK JUVENILE ASYLUM.

I DESIRE to confine my remarks to the treatment of typhoid fever, because I have recently revised my experience, with the result of reaching some decided views, which differ radically from those advocated here to-day, as well as from those entertained by the profession generally in this country, and, up to a recent period, by myself also.

These views are the result of mature deliberation and sifting of evidence afforded by clinical and experimental data obtained from various sources and compared with my own.

The various methods of treatment advocated during my professional career of thirty years are doubtless familiar to you. About ten years ago I had settled upon the Ziemssen graduated cold-bath treatment as the most promising, and I obtained more satisfactory results from it than from any other. Still, when other antipyretic methods came into vogue, with so much promise of success based upon the idea that the reduction of high temperature was the chief desideratum, it was natural for me to be carried away upon the tide which has so completely swept over the profession, especially as the treatment by cold baths involved so much trouble, and proved so disagreeable to many patients and their friends. Gradually the milder forms of bathing, by wet pack and sponging, with quinine, thallin, kairin, antipyrin, the ice-coil, and later antifebrin and phenacetin, have assumed potent sway over the profession.

A review of my experience in the last decennium, derived from personal observation in private and hospital practice, and in that of many colleagues, as well as from society discussions, develops the fact that the mortality of typhoid fever has not been reduced by the antipyretic method of treatment. I ask you to follow me carefully in a fair, conscientious, and exhaustive, yet brief, review of the results of the various methods in vogue during the past twenty-five years, and to compare it, as I have done for myself, with your own experience. You will then, I opine, agree with me that we stand to-day upon the threshold of a great epoch in the treatment of typhoid fever.

You have heard how fatal is typhoid fever at the present time, and I might offer you additional evidence by statistics I have gathered from the New York City Board of Health, from 1876–1885, during which time 7,712 cases of typhoid fever had been reported, with a mortality of 3,184, or 41.28 per cent. But as these statistics may be doubted by some, I will quote to you the mortality of typhoid fever in the New York hospitals, as stated by Dr. Delafield in 1885, which he has computed at 24.66 per cent. This mortality is even larger than that furnished by the recently gathered careful statistics in Germany, which show that, under the expectant treatment, of 11,124 cases the mortality amounted to 21.7 per cent. These statistics, to which others may readily be added, were they not sufficiently large, present to us the appalling fatality of typhoid fever under the now prevalent expectant, antipyretic plan, which seeks, by nourishing the patient, placing him in good hygienic surroundings, combating complications, and reducing the temperature, to conduct him to a safe issue. Much stress has, as you are aware, been placed during the past quarter of a century upon high temperature, as the predominating element of danger in typhoid fever. It has been claimed that parenchymatous degeneration of the heart, kidneys, and other organs was the direct result of prolonged high temperature, and the chief energy of therapeusis was expended upon this hydra-headed monster. This idea was indeed sustained by, if it did not originate in, the marvellous success of the cold-bath treatment, which Brand, of Stettin, brought before the profession in Germany, and which was adopted, after some modification, by Liebermeister, the high-priest at the altar of antipyresis, as well as by Juergensen, Ziemssen, and others.

The history of this special subject is indeed instructive, inasmuch as it illustrates how surely bedside experience will, sooner or later, demolish the most stately structures erected by theoretical reasoning. Brand never claimed that his bath treatment was chiefly directed against the high temperature. On the contrary, this was a secondary object with him. Liebermeister's criticism ("Handbook of General Therapeutics," William Wood & Co., 1885) is at once its best exposition and the highest encomium of Brand's method. On page 15 he says: "The work of Brand, which was published in 1861, ranks high above the level of the publications of the professional hydropathists of to-day. Still the author occupies pretty much the ground of Priessnitz. The pre-eminent importance of abstraction of heat is not sufficiently recognized, the main action of water is more that of stimulation," etc. Now, I propose to show that the stand-point of Brand is correct to-day, and that it is sustained by the most incontrovertible evidence of experimental study, seconded by clinical experience gathered from carefully recorded data. A few days ago I heard a faithful adherent of drug medication remark that it is singular how antipyretics are falling into disuse. Thinking men are indeed beginning to ask themselves the question: Has the introduction of these powerful antipyretics reduced the mortality of typhoid fever? Two years ago I answered this question in the New York Academy of Medicine, affirmatively, but I stated my belief that the small improvement was attributable to the comfort afforded the patient more than to the removal of danger from high temperature. To-day, after an exhaustive review of the whole subject, I am prepared to agree with Brand, that the only advantage from antipyretic medication seems to be that the patient is able to die with a nearly normal temperature. The fact that the statistics of private and hospital practice show a mortality reaching beyond twenty-four per cent. since the introduction and abundant use of antipyrin and its substitutes, proves their inadequacy. And the fact becomes more glaring when the statistics of the cold-water treatment reveal the astounding reduction of mortality to 3.9 per cent. We have reached a point in the study of this subject, so wrought with deepest interest, when it is our solemn duty to pause, weigh the reasons of this enormous difference in the mortality, and to ascertain if it may not be reduced. The purpose of this effort is to establish the fact that this mortality may be reduced by adopting the cold-bath treatment, and that it may even be reduced, as Brand has reduced it, to one per cent.! Those who, like myself, have personally witnessed the fatality of typhoid fever in our city, may, as I once did, shrug their shoulders in doubt. But if you will follow me in a brief analysis of the reasons for the faith that is in me, I hope to convince you that this is not a chimera, but a substantial fact based upon the most reliable clinical data.

Brand offers the statistics of 19,017 carefully gathered cases of typhoid fever (*Deutsche Med. Wochensch.*, 1887), which demonstrate that under the general influence of all kinds of cold-bath treatment, without, however, its strict enforcement, the mortality has been reduced from 21.8 per cent. to 7.8 per cent. But this is not all. As I have said in a recent paper read before the New York County Medical Society, Brand has obtained, from twenty-three German and French distinctly designated sources, the reports of 5,573 cases, statistical evidence which has not yet and cannot be controverted, and by which it is clearly shown that the cold-bath treatment originally recommended by him has reduced the mortality to 3.9 per cent. The latter, however, still contains many imperfectly managed cases. Eliminating these, the number treated strictly by Juergensen, Vogel, Brand, and others, up to January, 1887, amounted to 1,223 cases, of which twelve died, a

[1] Read before the Medical Society of the State of New York, February 6, 1889.

mortality of one per cent. And yet this is not all, for the most significant fact deducible from these statistics remains to be told. Not a single one of these twelve deaths occurred in any case that came under treatment before the fifth day.

Brand boldly asserts, on the strength of these 1,223 cases, of which he treated one-fourth in private practice, the remainder coming from Juergensen's hospital at Tübingen, Vogl's at Munich, and the military hospitals at Stralsund and Stettin, that all cases of typhoid fever coming under treatment before the fifth day should recover. Medical statistics are proverbially unreliable, but the exactness of the figures presented by Brand, in his able polemic in the *Deutsche Med. Wochenschrift* for 1887, cannot be doubted, nor the deductions gainsaid, because they are furnished from civil and military life, from university clinics and military hospitals, in which the cases were observed by competent and well-trained men.

Valuable as these statistics must be as an argument in favor of strict cold bathing, the results of the latter are better illustrated by some comparative statistics made by several clinical observers. For instance, the official records of the Second Prussian Army Corps, quoted by Brand, show that while, from 1849 to 1866, the mortality among 1,970 cases was 26.3 per cent., it was reduced, among 2,711 cases of strict cold-bath treatment, to 4.3 per cent. This enormous reduction is the more glaring when this mortality of 4.3 per cent. is compared to that of other armies; in the French army it was 32.2 per cent.; in the Italian, 28.6 per cent.; in the Austrian, 27.4 per cent.; and in the English, 23.8 per cent., during the same period. Indeed, so striking was the reduction of mortality wrought by this treatment in the German military hospitals, that the Prussian War Department deemed it incumbent upon itself to issue, on January 25, 1883, a circular to the medical service, in which it was urged that, inasmuch as the Brand treatment has been instrumental in reducing the mortality of typhoid fever in the various hospitals from twenty-five per cent. to eight per cent., "we are justified in expecting that, with an increased perfection and more general adoption of this treatment, it may become possible to save a still larger number of sick men."

The following table, which I have gathered with care to exclude all unreliable statistics, presents at a glance the comparative merits of the various methods of treatment.

Average Mortality under Various Methods of Treatment in Typhoid Fever.

Reporter.	Source.	Treatment.	Number of cases.	Percentage of mortality.
Brand.....	Various sources	Expectant	11,124	21.7
Delafield ...	New York Hospital, 1878–83.	Mixed expectant	1,305	24.66
Brand.....	Various sources	All kinds of cold baths.	19,017	7.8
Tripier, Bouveret, and Teissier.	Red Cross Hospital, Lyons: 1866–77.....	Expectant	229	26.2
	1873–81.....	Intermediate.....	629	16.5
	1882–87.....	Exclusive cold baths in severe cases.	376	6.9
	1887.....	Strict cold bathing ..	139	5.0
Vogl	Military Hospital, Munich: 1841–68.....	Without water, expectant (?).	5,484	20.7
	1868–81.....	Intermediate, with water.	2,841	12.2
	1875–81 (Second Division).	Baths and antipyretics.	702	7.6
	1880.....	Strict cold baths	498	2.7
	1882–87.....	Strict cold baths	141	3.5
	1882–87 (Second Division).	Increasing baths and abolition of antipyretics.	144	4.1
Ziemssen ...	Tübingen University Clinic for 1877–87	Graduated cold baths and antipyretics.	2,000	9.6
Naunyn	Königsberg University Clinic.	Strict cold baths	145	6.9
Brand.....	Collected from various sources.	Strict cold baths ...	2,198	1.7
Brand.....	Same cases, omitting those not treated before the fifth day.	Strict cold baths	2,150	0.0

The above figures astounded me when I sought them out, and I trust they will impress the lesson they teach indelibly upon your minds.

But I do not ask you to accept this statistical evidence alone, although you will doubtless concede that never in the history of medicine have statistics of such magnitude, from such reliable and diversified sources, been brought to bear upon a question of therapeutics.

Let us divest ourselves of the empirical influence of mere figures which, it has been said, may be marshalled in any cause to prove anything, and study the reason why the cold bath treatment of typhoid fever is superior to the antipyretic expectant plan.

In the first place, the idea that high temperature is the chief determining cause of fatality in typhoid fever must now be abandoned. The sooner we cut loose from this bugbear the better for suffering humanity. I am glad that Dr. Burt has taken strong ground on this subject. Rather than enter upon an elaborate discussion of the present status of the question, I will refer you to the clear and sagacious review of the pathology of fever by Professor Welch, of Johns Hopkins University, in his Cartwright Lectures last spring. Study these lectures carefully, and you will find a cautious, painstaking weighing of all the evidence bearing upon the lethal influence of heat elevation in fever, sustained by experimental and clinical data that must be convincing to any unbiased mind. He says, in summing up (THE MEDICAL RECORD, April 28, 1888): "We find that animals may be kept at high febrile temperature for at least three weeks without manifesting any serious symptoms. The only functional disturbances which could be attributed directly to the influence of the elevated temperature were increased frequency of the respiration and quickened pulse. No definite relation could be established between the variations of arterial tension which occur in fever and the height of the temperature. Although the experiments narrated showed that prolonged high temperature is an element in the causation of fatty degeneration of the heart, they also indicated that other factors, such as infection, are concerned in the production of the lesion. Moreover, experimental evidence was found in support of clinical facts, showing that this alteration may exist without serious interference with the functions of the heart, so that the conclusion seems justifiable that failure of the heart's power, in fever, is *less* an effect of high temperature than of other concomitant conditions. The lessened perspiration, the renal disorders, and the digestive disturbances (with the possible exception of constipation), are referable also chiefly to other causes than the increased temperature. Both experimental and clinical observations strongly support the view, now widely accepted, that the disturbances of the sensorium, which constitute so prominent a part of the group of so-called typhoid symptoms, are dependent in a far higher degree upon infection or intoxication than upon the heightened temperature. Although no attempt was made to analyze in detail the clinical evidence relating to the effects of high temperature, attention was called to the fact that the absence of all serious symptoms in many cases of relapsing fever, and in the so-called aseptic fever, in spite of prolonged high temperature, strongly support the conclusions derived from the experimental study of the effects of heat upon man and animals. Even in fevers, such as typhoid fever and pneumonia, where the height of the temperature is undoubtedly a most important index of the severity of the disease, there exists no such parallelism between the temperature and the nature and severity of the other symptoms, as we should expect if these symptoms were caused by the increased heat of the body."

I might offer you many clinical observations on this point, but two of these, from men whom you all know and honor, will suffice. In the discussion of a paper on antipyretics which I had the honor to read before the Section on Practice of the New York Academy of Medicine, the lamented Dr. Wesley Carpenter said that, "With regard to heart failure and degeneration of the muscular fibres of the heart, I had an opportunity, in connection with the pathological department of Bellevue Hospital, to ex-

amine microscopically the cardiac muscle in a sufficient number of cases to make it quite evident that it did not occur with the frequency one might be led to expect from reading the writings of the German observers."

Dr. A. L. Loomis said on the same occasion, "He was not certain, for he had been in the line of observations similar to Dr. Carpenter, that failure of the heart is due to parenchymatous degeneration, of which we have at times heard so much, and it had seemed to him to be due to failure in nervous supply as much as to muscular changes."

This is clear evidence from two pathologists and clinicians, which I might corroborate by other native and foreign testimony. Since it may be now regarded as an established fact that high temperature, minus infection, does not produce those serious degenerations formerly ascribed to it, we must seek in the infective process, and the ptomaïne-intoxication resulting from it, those deleterious effects upon the vital organs which undermine the system, and eventually cause death in typhoid fever.

The cold bath treatment yields the most triumphant results in combating these very effects of the infective and toxic agencies, with whose true entity we have not yet been brought face to face. It has been clearly demonstrated by numerous trustworthy observers, that the reflex stimulus aroused by the shock to the extensive peripheral nerve-endings so energizes the nerve-centres which furnish innervation for circulation, respiration, digestion, tissue formation, and excretion, that the system is enabled to tide over the dangers which would ensue from failure of these functions. This is the effect of cold bathing in a nutshell; the simple cooling effect on the blood occupies a secondary, though not unimportant, office.

The fact, as shown by Winternitz, Quinquand, and others, is that cold baths actually increase oxidation in health, and that while the skin is cooled and the blood-vessels contracted, the deeper structures are slightly increased in temperature and their vessels dilated. As the opposite condition, viz., dilatation of the arteries and superficial vessels, evidenced by the dicrotic pulse and loss of elasticity and contraction of the vessels, with diminution of the blood-pressure in the inner structures, are manifestations of the fever, the effect of the cold bath appears primarily to be directed against these manifestations, as has been demonstrated by Winternitz's sphygmographic investigations. The vivifying effect upon the nerve centres referred to produces a vigorous cardiac action, which is evinced by the slower and more regular pulse and an improved tension of the vessels; it improves the appetite and digestion, enabling us to enforce a more perfect nutrition; it deepens and slows the respiration, preventing stasis of bronchial secretions, and obviating pulmonary complications; all the secretions are enhanced; the patient is refreshed and invigorated, and fights the battle for life with all chances in his favor. How different is the aspect of the case under the expectant treatment, and how different is the effect of pure antipyretic medication! The temperature may indeed be reduced, but the stimulating effect upon the nerve-centres and secretion, except on the perspiration, is absent. Vinay (*Lyon Médical*, 1888), who has made some creditable investigations on the subject, tells us that the antipyrin does not relieve the delirium, which is in accordance with my own observation; it does not, like the cold bath, increase the flow of urine, by which noxious elements are eliminated. Vinay has confirmed Vogl's observation, that there was a rapid gain of weight after cold baths had reduced the fever.

Kairin, resorcin, and antipyrin diminish the excretion of urea and nitrogen; hence they diminish the excretion of the materies morbi through the kidneys, while baths increase it. The liver, in patients dying after treatment by antipyrin, is from 6 to 12.50 grammes heavier than in those dying after cold baths. Indeed, there is an entire absence of effect upon the circulation after antipyrin, an effect which is marked after the cold bath.

Briefly stated, cold baths are antifebrile remedies, while antipyretics are simply antithermic. Hence the superiority of the former over treatment by antipyretic medication. A mixed treatment is advocated by Liebermeister and Ziemssen. The latter, who is one of the staunchest defenders of the cold bath (not, however, as an antipyretic alone), regards the gradually lowered bath as better adapted to the exigencies of private and civil practice, while he concedes that the results of Vogl, and others, in military practice leave nothing to be desired. Liebermeister insists upon the cold bath as an antipyretic to produce remissions, and orders quinine to render these more enduring. Naunyn, on the other hand, uses a modified and more temperate bathing, rejecting all antipyretic medication.

The statistics of these different methods have been presented to you, and I have now added as briefly as possible the reasons why the results are more favorable in the cold bath treatment first suggested by Brand in 1861. The latter is thus demonstrated to be the ideal treatment for typhoid fever, and that, whenever a deviation is made from it, Juergensen's opinion, given at the Congress in London, is sustained, that "whenever he has attempted to deviate from the rigorous cold water treatment, he was compelled to return to it in order to obtain the best results." This then is the standard for our guidance. It is to be carried out as follows: Whenever the temperature reaches over 103° F. in the rectum, the patient is placed in a bath of 65° F. A half bath of this temperature, with affusions three or five degrees lower, is sometimes used. This is to be repeated every three hours, so long as temperature is not reduced below 103° F.; and the patient is to remain fifteen minutes each time. Patient should be gently rubbed while in the bath; when he is removed from it, he should be wrapped in a coarse linen sheet, the extremities dried and wrapped in a blanket, and a stimulant may be administered. In extreme cases of muttering delirium, or when there is decided adynamia, a stimulating bath should be administered, even if the temperature is below 103° F. This consists of a half bath in warm water with cold affusion. A wet compress should be kept over the abdomen constantly when patient is in bed. Judgment must be exercised to adapt the baths to the condition of the patient and stage of the disease. The Ziemssen bath, which may be used when the patient, his friends, or the doctor is timid, consists of submerging the patient into a partial bath, about 9° F. or 10° F. below his temperature, whenever the latter reaches 103° F. in the rectum. While two assistants gently play water over him and rub him, cold water is added gradually near the feet, until its temperature is lowered to 68° F. He remains altogether twenty to thirty minutes, or until there is decided chilliness and chattering of the teeth. (Simple pallor of the skin and smallness of the pulse do not indicate removal.) He is now removed and wrapped in a dry sheet. The bath is repeated as often as the temperature reaches 103° F. This bath also requires judgment, as does every valuable remedial measure. The clinical picture of a case of typhoid fever treated by cold bath, as given by Brand and Ziemssen, and as I have personally observed, indicates that the whole aspect of the case is changed; the patient is bright, cheerful, eats well, sleeps well, all his functions are properly performed, and what is most important, complications are prevented. Even disease of the intestinal glands does not go beyond infiltration, according to Brand, if the case be treated early.

Ziemssen and Vogl furnish from personal experience a description of the beneficial effect of cold baths upon themselves, when they suffered from typhoid fever. Vogl gives us a similar experience.

We must not be deterred by timidity from rigorously executing the plan of three-hourly bathing so long as the temperature is 103° in the rectum, or when the sensorium is deeply depressed with a lower temperature. Even sleep should not prevent resort to the thermometer and bath, if needed. The object of this treatment, it must

be understood, is not to subdue the temperature, but to vivify and energize the vital organs, and thus insure a vigorous resistance to the toxic influences arising from the infective processes. This is the great aim to be kept steadily before us.

In presenting this apparently heroic treatment to the reconsideration of the profession, I am aware that there are serious objections to its general adoption, which seem almost insurmountable. The profession must first be educated to abandon the policy of expectancy, whose aim it is to allow the fever to pursue its own course:

1. The annoyance to the patient is not in accordance with the expectant plan, whose object it is to avoid all disturbance of the patient for remedial purposes. So long as we had only an inefficient, if not injurious, medicinal treatment, it was wise to avoid disturbing sleep. But, in a severe case of typhoid fever, it is as important to disturb sleep when the rise of temperature indicates the necessity, as it is in opium-poisoning when stupor supervenes. Indeed, the treatment is somewhat analogous, inasmuch as the object is to arouse the nerve-centres, and keep them aroused (though not continuously as in the latter), until the toxæmia has passed away.

2. The nurses and friends of the patient will be reluctant to adopt so active a measure. If the physician is convinced that he is right, he must insist upon his directions being followed.

3. The idea that the reduction of temperature is the leading object of the cold bath, and the much greater facility of accomplishing this object by antipyrin and antifebrin, may deter many from adopting the former. The fallacy of this course has been demonstrated.

4. Timid persons may be alarmed by the patient's pallor, small pulse, and complaints of chilliness while in the cold bath. But if properly administered, with chafing of the body and limbs, these effects will be counteracted to some extent. Reaction after removal will soon reassure the attendant, and embolden him to order a regular repetition.

5. A slovenly application of the bath, or the substitution of some other method—packing, sponging, sprinkling, etc.—will fail and cause discouragement. It must be remembered this is not *cold bathing*. A small experience, personal or from hearsay, which may have been unfavorable in one, two, or several cases, will deter some from adopting the energetic cold bathing. An intelligent hospital physician told me yesterday that he was discouraged from the cold-bath treatment by witnessing, while an interne in one of our hospitals, the death of a patient after being placed on a Kibbé cot, wrapped in a sheet, and *sprinkled with ice-water* for a considerable time. This method is not recommended by any author whom I have quoted, nor is it even to be compared to Currie's cold affusion, in which the stimulus of impingement of a large mass of cold water upon the surface favors rapid reaction, with its resultant stimulating effect on the nerve-centres.

The only modification of the general cold bath admissible is the stimulating affusion advised by Brand in cases threatening heart failure and delirium. This is a warm half-bath, with cold affusions over the head, chest, and back. (One important point is that the tub should always be brought to the bedside, to avoid unnecessary disturbance of the patient.)

6. The experience with cold bathing in England and America, where it has never found favor, has been too small to afford a proper estimate of its value. Dr. Bristowe, of St. Thomas' Hospital, opposes it; he says: "My personal experience in this treatment is not extensive, and for some years I have rarely, if ever, resorted to it. I have undoubtedly seen patients apparently benefited and making a good recovery. But I have never felt satisfied that the benefit was real."

Dr. Austin Flint published, in 1882, a lecture which exercised a potent influence in this country. He treated seventeen cases in Bellevue Hospital. "In a few cases the cold bath of 80° F., gradually reduced to 65°, was employed, but was discontinued on account of the inconvenience." His conclusion was that the antipyretic treatment neither increased nor diminished the mortality, which was four out of these seventeen cases.

Compare these statistics with those offered by Brand, and their utter insignificance for purposes of deduction is apparent. The prejudice existing against the cold-bath treatment is illustrated by a passage in "Struempell's Practice," a translation of which is now used as a text-book in the College of Physicians and Surgeons of New York. Struempell says, with his usual fairness: "There is at present no other single method of treating typhoid fever which has so numerous and evident advantages for the patient. We regard it as the duty of every physician who undertakes to treat a severe case of typhoid fever to try his best to have the bath employed." The editor and translator (a noted hospital physician) endeavors to neutralize this recommendation by stating that, "notwithstanding the high praise bestowed on the cold-bath treatment in Germany it has never become popular," and quotes Senator's statistics in support of his position. This is a serious misstatement, because Senator distinctly says (*Berl. Klin. Wochensch.*, 1885, p. 758): "If my essay has made the impression that I oppose cold baths, I must have expressed myself very badly."

7. One objection to the strict execution of Brand's method is doubtless the difficulty, if not impossibility, of treating patients before the fifth day. Indeed, this can only be done in military hospitals or in epidemics. Every suspicious case should be subjected to the bath. At any rate, the more nearly we approach the high standard of strict bathing, the more nearly we will approach the low mortality. Hence the earlier the baths are resorted to, the more strictly in accordance with the directions regarding their temperature and frequency, the more completely will the toxic processes be controlled and the mortality be reduced.

In conclusion, let me urge upon you to carefully weigh the evidence I have so imperfectly presented, and to seek in the literature of the past two years further information ere you decide to reject it and to continue the present fatal expectant-antipyretic course of treatment. As I have elsewhere said: The history of medicine does not present a parallel to the application of statistics for the elucidation of a question of therapeutics which Brand has presented and which I have amplified. The evidence is before us, clear and uncontrovertible. Upon our conscientious, unbiassed, and fearless judgment and action rests the weal or woe of those who commit their lives into our keeping.

47 East Sixtieth Street.

Triple Delivery by Cæsarean Section.—A curious case of triple birth took place last week in the Lariboisiére Hospital. A few days previously a poor woman entered the hospital in an advanced stage of pregnancy. The house-surgeon, after a careful examination, told her that in all probability she would give birth to three children. She had already four dependent on her. The surgeon left her in charge of the midwife, who was a very intelligent woman, as will be seen. The poor woman, evidently in the throes of labor, paced up and down the room, when suddenly she was seen to stagger and clutch at the window frame near which she was standing. The attendant rushed to her aid, but she was dead. The midwife having rapidly taken in the situation, and knowing that at the moment no doctor was at hand, decided on extracting herself the unborn children. The necessary instruments having been obtained, she boldly performed the operation, and brought into the world alive two girls and one boy. Great sympathy has been felt for them, and naturally great admiration for the heroic conduct of the *sage-femme*. The *Figaro* has opened a subscription list for the children.—Paris Correspondent of the *Medical Press*.

COMPOUND DEPRESSED FRACTURE AND LOSS OF SUBSTANCE OF THE FRONTAL BONE—ENCEPHALITIS—EPILEPSY—DEATH.[1]

By WILLIAM A. HUME, M.D.,

NEW YORK.

A MAN, aged thirty, was injured, May 10, 1886, by the explosion of a steam-drum over which he was working. The heavy pieces of metal struck his forehead, lacerated the skin, and fractured the frontal bone just above the orbits. The fractured bone was comminuted and depressed, the membranes of the brain were lacerated, as was also a portion of the cortical substance of the right frontal lobe, and the superior longitudinal sinus was opened, causing considerable hemorrhage. There was little or no shock, and the patient did not lose consciousness. The depressed fragments of bone were removed, and the projecting sharp edges of bone remaining intact were cut off with rongeur forceps. The loss of bone substance was considerable, the opening being nearly oval in shape and measuring, at widest points, seven centimetres laterally and three centimetres from below upward, situated somewhat obliquely on the right, a little above right orbit, from which point the lower border extended downward and to the left, crossing nasal eminence and involving the left orbital plate. The loss of bone substance was about equal on either side of the median line, so that both frontal lobes of the brain were exposed.

It may be of interest to refer to one or two points of treatment. The hemorrhage from the superior longitudinal sinus ceased spontaneously, probably from the formation of a thrombus within the sinus. The edges of skin wound were sutured together and union by first intention took place; but later, from pressure of brain, several ulcerations occurred along the line of union, the entire line gave way, and brain substance protruded through the wound, completely filling the opening in the bone, and projecting externally to the extent of from one to two centimetres. Over this hernia cerebri compresses and bandages were applied, and so, by gradual pressure, the brain substance was replaced. The skin wound healed by granulation. Notwithstanding the injury to the brain and to the membranes, the head symptoms during treatment were slight; the patient was delirious once, but only for a short time, and the temperature was not much above normal.

For several months the patient seemed to have made a complete recovery, and during that period the late Dr. Sands exhibited the case to the New York Surgical Society; but eight months after his injury the patient had an epileptic attack. The paroxysm was not severe, he was given bromide of potassium, ten grains three times a day; this quantity was gradually increased to twenty grains four times daily, but this amount producing "bromism" it was reduced to ten grains four times a day, and so continued. The epileptic attacks recurred at intervals of about eighteen months, not more than one attack at a time, and, as far as could be learned, were never limited to one side of the body; it is probable, however, that a local spasm first occurred, which very quickly became general, and all parts of the body were convulsed. The sense of smell was not affected, as might be supposed from location of brain lesion (to be described later), the olfactory nerve with its bulb being on either side of the longitudinal fissure, upon the under surface of each anterior lobe. The patient very seldom had headache, and never experienced an epileptic aura.

Ordinarily the skin covering the opening in the bone would advance and recede with each pulsation of the brain, but this was not so during a fit. I had an opportunity to observe the head-wound in one of his paroxysms. The skin was firmly drawn back through the bone opening, and the pulsations were no longer visible. This condition remained unchanged until the period of stupor, when the pulsations gradually became more and more pronounced, and, as consciousness returned, the skin projected a little beyond the level of the surrounding integument; its usual position was slightly sunken. It seems to me this fact is of value in support of the supposition that during an epileptic attack all but the initial phenomena result from vaso-motor disturbance, the cerebral arteries are contracted, and consequent anæmia of the brain ensues. We seldom have any indication, through so large an opening in the head, as to the changes in the intracranial blood-vessels during an epileptic attack. Küssmaul and Fenner have made observations to prove that during an attack of epilepsy the brain is anæmic, and it is a well-known fact that, both in animals and in man, loss of blood may be followed by convulsions. Three months before death the epileptic seizures increased in frequency and in violence, occurring about once a week with, often, two or three attacks at a time. The post-mortem examination of brain gave evidence of recent lesions to account for this. The intellect was not at all impaired until this time, when he had marked failure of memory. This was probably due to the frequency of the attacks. During the last week of life the fits were of nightly occurrence, and during the twenty-four hours preceding death the patient had sixty paroxysms. They occurred in such rapid succession that before he could recover consciousness from one fit another had commenced, and in this condition, "status epilepticus," he died, November 10, 1888. At autopsy the margins of bone were rounded off by absorption. Firm adhesions existed between the skin, membranes, and brain. The dura had not entirely reformed, and the anterior portion of the right frontal lobe was uncovered by it. The pia over the anterior portion of the right frontal lobe was entirely obliterated, and the anterior part of each frontal lobe was softened and disorganized, but particularly marked in right lobe.

I wish to express my indebtedness to Drs. E. C. Spitzka and N. E. Brill for their kindness in making post-mortem examination of the brain. Dr. Spitzka furnished the following notes as the result of such examination, and cross-section diagram showing the lesions in the right frontal lobe. The diagram shows the posterior face of a section anterior to the anterior end of the caudate nucleus.

"Over the anterior part of the convexity of the right frontal lobe, in a line running in the frontal plane, convex upward for four and a half centimetres, then dipping down acutely for two centimetres, the dura and pia, indistinguishably fused, appeared drawn into the cerebral substance. The line in question corresponds nearly to the course of the gyrus frontalis marginalis. At and below it the fused membranous investment was firmly united to a trabecular tissue, varying in thickness from one and a half to three millimetres, and covering a cavity of a linear direction following the line of attachment above described. Its dimensions could (from the ragged nature of this part of the specimen) not be accurately ascertained; it was irregular, and three spurs from it are exposed in the cross-section diagram accompanying. At its periphery the investing tissue merged gradually into the normal cortex of the neighboring gyri. The latter were puckered in toward the cicatrix, thus presenting a sort of radiating disposition.

[1] Read at a meeting of the New York Pathological Society, December 12, 1888.

of these gyri, in great contrast with the normal disposition of the left lobe. The right frontal lobe, as a whole, appeared smaller than its fellow.

"On making sections at brief intervals, it was ascertained that pathological appearances visible to the naked eye extended through the white matter, under the affected area, nearly to the frontal plane of the anterior end of the caudate nucleus. While the cortex of the anterior ends of all three frontal gyri, and in part the subcortical white matter, appeared of normal consistency and color, aside from the area immediately involved in the cicatrix, a large part—what may be called the 'core' of these three gyri—was converted into a spongy tissue, of the kind which is described by authors as resulting from rarefying encephalitis. Its centre was a finely meshed tissue, compressible and very nearly like a sponge in texture and feel. In the axis of the middle frontal the meshes appear wider, more honeycombed. The process did not appear equally advanced in all parts. The meshes were firmest, and the walls of the cavity most sharply defined, in the middle frontal, and least so in the orbital transition of the lower frontal, where there was an area of very recent lacunar softening. As a rule, the meshes appeared to follow the course of the nerve-fibres. The second section revealed a distinct fibrillation in the course of a projecting end of two arcuate fasciculi, comparable to that observed in fracture of the normal hardened brain."

MEDICO-LEGAL CASES IN THE COURTS.

By HENRY A. RILEY, ESQ.,

NEW YORK.

The decisions regarding the inherent right of municipalities to pass regulations for the public health are becoming very numerous, and form a body of law approaching in importance that of any other department of jurisprudence. The tendency in the decisions is to restrict private rights and to show to boards of aldermen how practically uncontrolled are their powers in many directions. An ordinance hurriedly passed and without careful consideration may often work serious injustice and not be really demanded by regard for the public health. Whether this is true in the following instance it is impossible to tell at this great distance.

A city ordinance of Mobile, entitled an "ordinance to establish and regulate markets," provided that no fresh meat should be sold outside of certain markets established by the ordinance.

This naturally broke up the business of many persons, who felt that their constitutional rights to freedom of trade had been infringed, and an appeal was made to the courts to declare the ordinance unconstitutional. The tribunals ruled, however, that the ordinance did not exceed the powers of the city authorities. They did not, indeed, have power to prohibit entirely the trade in fresh meat, but they could regulate it, which involved the idea of prohibition in certain localities, provided it appeared that the public health demanded the concentration of the traffic. The important point in this decision, as in all others of the kind, is that practically there is no way to control city authorities in their determination of what the public health demands. This almost unlimited power is a matter of serious importance, though it cannot be said that it has thus far been exercised so as to work gross injustice.

It may be noted, however, that the courts will exercise control in cases where it is evident that some other reason than the public health prompts a municipal ordinance. Take, for instance, the law in this State, passed a few years since, prohibiting the manufacture of cigars in certain rooms of houses in New York City, and in certain houses entirely. The circumstances surrounding the origination of this law seemed to show to the courts that the endeavor to stamp out competition was the controlling motive of the law and not a regard for the public health. Taking this view, the courts held that the conceded power of the Legislature to regulate the cigar manufacture on real considerations of public health could not be used to aid a monopoly, and the law was declared unconstitutional. It would be of great value, as showing the drift of the law, if the decisions of the last few years on questions of public health were gathered together and properly collated.

The accident insurance companies desire the public to believe that they give ample protection against all injuries resulting from accident, yet claims are often refused payment which seem to come under this head.

The Fidelity and Casualty Company not long since defended a suit on a policy where the facts were as follows: A person insured against accidents was driving upon a public street, and his horse became frightened at some object and ran away without upsetting the carriage or coming in contact with anything, and was at length brought under control. The insured was apparently greatly endangered at the time and suffered so severely, either from fright or strain caused by his physical exertion in restraining the horse, that he died within an hour afterward. Under these circumstances, the court held that the death ensued from bodily injuries effected through "external, violent, and accidental means." Certainly there was an accident. The definition of "accident" usually assented to is an event happening without any human agency, or, if happening through human agency, an event which under the circumstances is unusual and not expected to the person to whom it happens. This definition exactly suits the facts here. Argument cannot be necessary to satisfy anyone that the injury happened by violent means. A well man suddenly meets a perilous emergency which taxes all his physical and mental strength, and his death is thereby caused in an hour. The greater question is whether the death was caused by external means. We have no doubt that it was. All the evidence that we have, more than the facts already stated, is that the insured became deathly sick, and after death a discoloration appeared on the surface of the body in the region of the heart. There is no pretence that the body bore any marks of contact with anything inflicting injury, or that it came in contact with any physical object during the time of the accident.

Our belief is that, on the facts legitimately before the court, the death was produced by a ruptured blood-vessel about the heart, and that such rupture was caused by the extraordinary physical and mental exertion which the deceased put forth to save his children and himself from injury. The jury decided that the policy of insurance must be paid, and this verdict was upheld by the appellate court.

The mode of execution by electricity which was recommended, not long since, by the Committee of the Medico-legal Society of this city, is as follows:

A stout table, covered with rubber-cloth, and having holes along its borders for binding, or a strong chair, should be procured. The prisoner, lying on his back, or sitting, should be firmly bound upon this table or in the chair. One electrode should be so inserted into the table or into the back of the chair that it will impinge upon the spine between the shoulders. The head should be secured by means of a sort of helmet fastened to the table or back of chair, and to this helmet the other pole should be so joined as to press firmly with its end upon the top of the head. We think a chair is preferable to a table. The rheophores can be led off to the dynamo through the floor or to another room, and the instrument for closing the circuit can be attached to the wall. The electrodes should be of metal, between one and four inches in diameter, covered with a thick layer of sponge or chamois-skin. The poles and the skin and hair at the points of contact should be wet with a warm aqueous solution of common salt. The hair should be cut short. Provision should be made for preventing any moisture reaching from one electrode to the other. A dynamo capable of generating an

electro-motive force of at least three thousand volts should be employed, and a current used with a potential between one thousand and one thousand five hundred volts, according to the resistance of the criminal. The alternating current should be made use of, with alteration not fewer than three hundred per second. Such a current, allowed to pass for from fifteen to thirty seconds, will insure death.

The mode of execution above described, or any other which may be devised, will not be made use of for some months at least, as the law prescribing the use of electricity only applies to murders committed after January 1, 1889. Many of the papers have, however, been imagining, with a grim humor, the strange scenes which may come to pass when the law is finally invoked. A writer in the New York *World*, for instance, suggests the following as a scientific sentence to be pronounced by the judge: "I therefore sentence you to be taken to Sing Sing prison, there to remain confined until ...., the .... day of ...., 188.., between the hours of .... and .... A.M., when you will be taken to a cell specially designed for that purpose, be forcibly seated in a properly insulated chair, with one semaphore placed upon the junction of your frontal and parietal sutures and the other just over your medulla oblongata and then and there made conductor for an alternating current of 1,800 volts intensity, from a dynamo constructed for that specific purpose, said current to pass through the ganglia and vasomotor centres of your cerebral tissue until you are dead, dead, dead; and may the Lord have mercy on what is left of you."

There was a recent case in Massachusetts where a manufacturer made use of a new chemical in dyeing cloth, and a purchaser was poisoned by handling it. In an action for damages it was held that the manufacturer was not liable, as the injury was the first known instance of harm resulting from the use of the mordant.

The Board of Health of Illinois a few months ago revoked the license of H. G. Wildman, a physician, the chief charge being that he had overstepped the ethics of the profession by advertising his success and skill in newspapers. Dr. Wildman then appealed the case to Governor Oglesby, and he rendered his opinion a few days since, reversing the decision of the Board of Health, and claiming that a physician should not be debarred from practice because he advertises what he can do and has done. Dr. Wildman expends over $40,000 yearly in advertising in papers all over the Union, and several of the Illinois papers went on his bond in the action. The decision has caused considerable comment in the West.

Danger in the Postage Stamp.—The *Sanitary News* calls attention to the fact that a postage stamp may in various ways convey contagion. One of the simplest and most plausible is that in which a postage stamp, partially attached to a letter to pay return postage, is sent by a person infected with some disease to another person. The disease is transferred in the first place to the adhesive stamp through the saliva, and in being attached to the letter by the receiver the poison may be transmitted to him in turn through the saliva. Another cause may be the infection of the stamp with disease germs. The stamp, having been exposed in a room where a diseased person lies, may become slightly moistened and thus retain the germ. That this is true can be proved very simply by a microscopical examination. We often see a person holding change for a moment in the mouth, probably not knowing that investigation has shown that disease germs can be carried by money. If one could see through what hands the money has passed they would hesitate before using such a third hand. Silver money is as bad as paper money, but while many would hesitate to hold a dirty bank-note in their mouth, they think that a silver piece, because bright, is apparently clean.

Progress of Medical Science.

Electrolysis in Angioma and Goitre.—Mr. John Duncan has recorded his experience in the treatment of nævi, cavernous angioma, pulsatile angioma, and goitre, by means of electrolysis. Many of the cases which he details were of extreme gravity, and had been rebellious to other treatment. His results in the angiomatous cases were uniformly successful (*The American Journal of the Medical Sciences*, January, 1889). He worked with a current of between forty and eighty milliampères, but considers that really a matter of small importance. A galvanometer is of no value in operations where the duration is determined by the palpable and visible effects produced. It is very different in cases in which we cannot see and feel the gradually increasing swelling, tension, and hardness. Here a means of measuring the current in operation is essential. Five to eight cells of large size and good electro-motor force are most convenient to work with. It is not necessary to use a large number of cells if both poles be introduced as they ought to be. The body is as good a conductor as acidulated water, if the resistance of the skin be avoided. He introduces both electrodes (insulated, so that the operation may be truly subcutaneous), but works chiefly with the negative pole. It is to be remembered that the effect is produced invariably by shrivelling up and destroying the vascular walls; and that coagulation of the blood is a matter of very secondary importance; therefore he keeps moving the negative pole about, and penetrating as many vessels with it as possible, because its destructive effect is more powerful and diffuse than that of the positive. He maintains it in one place just long enough to bring about a decided effect, and then changes to another. In these operations the process is essentially distinct from that by which Apostoli and others have produced their effects upon uterine tumors. However his results may be brought about, it is not by electrolysis proper, it is not by the decomposition of fluids and solids at the poles of the battery. It may be neurotic, or vascular, or trophic, or osmotic; it is not electrolytic, and to call it so is no doubt a misnomer. Mr. Duncan says he has not yet had sufficient experience to be able to define with precision the value of electrolysis in goitre, but he gives the results, so far as they have gone, of fourteen cases. Three are still under treatment, having been recently operated upon, and already showing beneficial results. One is a fibro-cystic, another a strongly marked exophthalmic, the third a vascular goitre, with considerable dyspnœa. Eleven remain, two or three having slight vascular and exophthalmic symptoms, others with slight dysphagia or dyspnœa, all of the vascular variety. Four of them it was impossible to trace. These cases were in the infirmary for only a day or two, and the records of their addresses have been imperfectly kept. In two cases, however, they returned for a second operation, having been benefited by the first. Of the others, six have been absolutely cured, and the seventh has the tumor still in no way changed by one operation. Mr. Duncan thinks that these results are very encouraging, and that with greater experience we will be able to operate with more confidence. The chief difficulties have hitherto laid in the manipulation of the needles, and our want of knowledge of the effects which might be produced on surrounding structures in so important a locality.

Restricting the Use of French.—The physicians of Alsace-Lorraine have been informed that henceforth they must write their prescriptions in German or Latin, and not in French, as has been their custom. This is, of course, in the line of the German policy to root out the use of the French language in the conquered provinces, and is a national sequence of the decree forbidding the use of French in the transactions of medical societies.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 16, 1889.

CONSUMPTIVE TRAVELLERS.

WE have received a reprint of an article published in the *Australasian Medical Gazette* for November, 1888, by Mr. G. R. MacMullen, in which attention is directed to the dangers to which consumptives, seeking a more propitious climate, expose their healthy fellow-voyagers. This thought must often have occurred to many who have travelled with such patients; but, owing perhaps to a feeling of delicacy and a desire to avoid wounding the susceptibilities of the afflicted, it is seldom that the question is discussed openly.

The author, who is a layman, has apparently experienced that of which he writes, and expresses himself with decision, though withal as delicately as the subject will permit. He cites the case of a traveller going from London to Australia, who secures a berth in a cabin and finds that his companion for the voyage is one with well-marked phthisis. The state-room is probably very small, and there may be two, three, or four berths in it. The sick man will naturally have a considerable dread of ventilation, at least of such an amount of it as a healthy man would desire, and even if he has not, the ventilation of the state-room is at best by no means perfect. The well man will have a natural repugnance to insist on the greatest possible amount of ventilation when the carrying out of his wishes will subject his suffering companion to the real or fancied dangers of cold air or draughts. And even should he assert his undoubted right to a fair amount of fresh air in the cabin, he knows that in so doing he causes much physical or mental suffering to his already afflicted room-mate, and consequently what little pleasure he might have derived from the voyage, in the intervals of sea-sickness, is marred by his self-accusations of lack of consideration for the feelings of his room-mate.

But if this were all it would not be worth mention. It would be merely an occasion for mutual concessions which are demanded of every one who is thrown in the company of another, whether for life as man and wife, or for a brief period as fellow-travellers by land or water. All who believe in the contagiousness of tuberculosis will see in such an association a real danger to the healthy party, and one which may well cause him alarm. If phthisis is contagious, and who is there that doubts it, no more favorable conditions for the transmission of the disease could be found than those present in the case cited by Mr. MacMullen.

The remedy, of course, consists in isolation, or at least in the separation of the sick and the well, though it is difficult to say just how this should be accomplished. The author proposes that the medical officer of the ship should have the power to remove such patients to the hospital during the voyage. But this seems to be an unnecessary hardship, and one that should not be inflicted upon the sufferer if it were possible to avoid it. It might be feasible to put two persons having the same disease together in one state-room, or to give each one a cabin by himself. It is, at all events, a subject that is worthy of consideration, and doubtless some means might be devised whereby the rights of the healthy could be preserved without the infliction of physical or mental distress upon the suffering consumptive.

THE COLD-BATH TREATMENT OF TYPHOID FEVER.

THE argument in behalf of the cold-bath treatment of typhoid fever, made before the State Medical Society, and which is presented in full in this issue, moves us to a consideration of this oft-discussed theme.

The numerical method is open to many fallacies, and may be quoted in any cause. But it strikes us that when upward of thirty thousand cases are gathered from many and various sources, civil and military, we must give heed to the deduction from them.

If Dr. Baruch succeeds in arousing the profession to a realization of the fatality of typhoid fever in our midst, and in directing attention to the success of the cold-bath treatment, which, for obvious reasons, has not yet obtained firm footing, the outcome may be valuable.

Certain it is that we cannot dispute the important deductions from the comparative statistics cited, nor should we allow preconceived notions to deter us from utilizing them.

It will be difficult to persuade the profession, which has been so long under the dominion of the *laissez-faire* policy, to adopt the heroic method of cold bathing. There seems, however, in the points made by Dr. Baruch, sufficient ground to enlist our careful reconsideration of the whole subject. The most important of these seems to us the emphasis placed upon the object of the cold bath being anti-febrile rather than merely antithermic, inasmuch as its action is chiefly directed toward the neutralization of the febrile toxæmia due to the typhoid process. The secondary position assigned to elevated temperature as a lethal factor, may be amply sustained by recent clinical observations; for instance, Glasser has shown that among two hundred fatal cases only fifteen had manifested high temperatures during life. Lowering temperatures is not a curative measure.

The chief obstacle to the adoption of the cold-bath treatment will be the difficulty of convincing the physician that the small pulse, pallid surface, and marked chilliness, which patients manifest in the bath, are not harbingers of danger and death from heart-failure and collapse. That this fear is not as well founded, and that these symptoms of pseudo-collapse may be, to a great extent, obviated by energetic friction in, and rapid drying after, the bath, we are assured by trustworthy observers, all of whom agree that the cold bath is a true heart-tonic. Besides Brand, such clinicians as Liebermeister, Jacksch, Flehne, Strumpell, Rossbach, Heubne, Juergensen,

Bamberger, and others, have expressed, at the Congress for Internal Medicine in 1885, almost unanimously, the opinion that, until we find a specific curative agent for typhoid fever, that treatment is to be preferred which is capable of most successfully diminishing or removing the effect of the morbific agencies, and that this is most surely accomplished by the cold bath.

THE LATE PROFESSOR DALTON.

THE death of Dr. Dalton removes another of the eminent medical men of this city and country. Though not an old man at the time of his death, his scientific reputation was achieved so early that he has been classed among the pioneers and fathers of American medical science. Dalton's "Physiology" is a text-book familiar to thousands of American physicians. At the time of its publication, and for years after, it was the best English work on this subject, and its influence upon medical teaching and thought has been very great.

Professor Dalton's best work was embodied in his "Physiology." His only other important contribution to the medical sciences was his "Topographical Anatomy of the Brain."

Professor Dalton combined in a happy manner the scientific spirit with literary skill and aptitude for teaching. He was popular as a lecturer, most interesting as a writer, and was admired and esteemed as a man. Professor Dalton was, with all this, a man of the world, observant, shrewd, and wise. These traits gave him still greater influence in his educational work, and in the management of the College of which he was president at the time of his death.

OLIVER WENDELL HOLMES' LOVE FOR HIS BOOKS.

DR. HOLMES has recently presented his library of works on medicine to the Boston Medical Library Association, of which he was once the President, thereby, as it were, breaking the last strand of the cord that bound him to the profession of medicine. It is hard to break up old associations and to sever ties of many years' duration, and we can well appreciate the reluctance that he must have felt in thus parting with his silent friends. It is now several years since he retired from the medical profession, yet it is only within the past month that he has relaxed his hold on the books which were the companions of his professional life. "A scholar should not be in a hurry to part with his books," Dr. Holmes once said, but his love for his fellows has conquered his love for his books, and he has placed the latter where they may benefit to the fullest extent those who follow him in the paths of medicine.

In his address on the occasion of the presentation of these well-beloved volumes, after reviewing the better books of the library and alluding to the private library that a practitioner should keep, Dr. Holmes continued his address by saying: "These books are dear to me; a twig from some one of my nerves runs to every one of them, and they mark the progress of my study and the stepping-stones of my professional life. If any of them can be to others as they have been to me, I am willing to part with them, even if they are such old and beloved companions."

After listening to these words, his hearers must have felt that this was indeed the breaking of the last link in the chain that bound the speaker to medicine, but they doubtless felt, as do we all, that they could never let him go, that they must hold him in spite of himself, and that they would ever, in his own words, "claim him, keep him, call him brother still."

MEDICAL WAR IN ST. LOUIS.

THERE is reported to be a small tempest in the medical circles of St. Louis. The cyclonic focus is the St. Louis Medical Society, an ancient and respected medical organization. At its annual meeting in January, so accounts run, there was a contest for the office of president between the conservative portion, and a number of aggressive members more or less connected with the *Weekly Medical Review* of that city. The latter gentlemen had been accused of using the *Review* for advertising purposes, its first page being decorated with a list of associate editors, each with his own specialty or generalty printed after his name. So bald an announcement of one's devotion to a single line of practice was severely condemned as unethical by the party of the Extreme Right. The fight in the Medical Society resulted in the election of the conservative candidate, whereupon the defeated faction has withdrawn and organized a duplicate St. Louis Medical Society. War now reigns, therefore, and the question which is the real, original society may have to be taken to the courts. It has, unfortunately, already reached the daily press.

We tender our respectful condolences to the brethren of St. Louis. Quarrels are always sad affairs, yet they excite a large degree of human interest, especially doctors' quarrels; for they show up the elemental nature of man in a way not brought out by the ordinary incidents of life. If our St. Louis brethren are bound to fight, we trust they will make it interesting, and will give and take the blows in a straightforward and hearty fashion. As for the merits of the controversy, it seems very unwise to have attempted any censorship of the alleged advertising methods adopted by those connected with the *Medical Review*. The practice complained of is one that concerns questions of good taste and expediency, rather than ethics. Those who follow so-called "business" methods in attempting to get a knowledge of their medical wares before the public, had best be treated simply as persons lacking in wisdom and sense of propriety. Censorious criticism and persecution will do no good. On the other hand, the recalcitrant advertisers who have gone off and organized a second society, have shown a greater desire to achieve personal success than to promote the harmony and best interests of the profession. Their legal title to be called the St. Louis Medical Society is of the most questionable kind.

A DEATH UNDER CHLOROFORM occurred a short time ago in the Cleveland City Hospital. The patient was about to be operated upon for enucleation of the eye, and considerable difficulty was experienced in bringing him under the influence of the anæsthetic. Just before the completion of the operation he recovered consciousness, and a few more whiffs of chloroform were given, when the heart ceased beating. Every effort was made to resuscitate him, but without success. At the autopsy the right heart was found dilated, although the valves were normal.

News of the Week.

THE MIDDLETON GOLDSMITH LECTURE for 1889 will be delivered before the New York Pathological Society by Reginald H. Fitz, M.D., Shattuck Professor of Pathology in the Harvard Medical School, Boston, at the New York Academy of Medicine, 12 West Thirty-first Street, on Saturday, February 16, at 8.30 P.M. Subject: "Acute Pancreatitis, with an Especial Consideration of Pancreatic Hemorrhage, Hemorrhagic Pancreatitis, and Subperitoneal Fat Necrosis." Members of the profession are cordially invited.

THE LANGENBECK MEMORIAL FUND AND THE NEW YORK SOCIETY OF GERMAN PHYSICIANS.—In the issue of THE MEDICAL RECORD of February 2d, page 131, in a paragraph commencing, "The largest medical society in Germany," etc., it is said that Professor Virchow announced that the New York Medical Society had contributed 1,000 marks to the Langenbeck Memorial Fund. It should read, the New York Medical Society of German Physicians.

POST-GRADUATE HOSPITAL EXTENSION.—Besides purchasing the property occupied during the past five years, Nos. 224 to 230 East Twentieth Street, at $60,000, the property adjoining has been leased for ten years, for the purpose of increasing the babies' wards of the hospital. The former ward for infants will be converted into a lying-in ward.

PUBLIC MEDICAL LIBRARIES.—In the proceedings at the reception given to Dr. Oliver Wendell Holmes, on the occasion of his presenting his library to the Boston Medical Library Association, Dr. R. M. Hodges, President of the Association, gave some facts regarding the public medical libraries of this country. "First," he said, "in point of time is the library of the Pennsylvania Hospital, founded in 1760; second, that of the College of Physicians in Philadelphia, founded in 1788; third, the New York Hospital Library, in 1796, etc. Of course the library of the Surgeon-General's office has surpassed in size all these, having a large annual appropriation and a magnificent librarian. Next in rank comes the library of the College of Physicians; next, that of the Academy of Physicians, and our library comes fourth in rank. After that come the Medical Department of the Public Library of Boston, and the New York Hospital Library. In other words, although the youngest of these seven libraries, ours has already passed three of them. We have nearly 20,000 volumes."

A SPECIFIC FOR CHOLERA.—Dr. Löwenthal thinks that he has found in salol a specific for cholera.

THE JANITOR AND A STUDENT of the Baltimore College of Physicians and Surgeons were convicted of breaking open a vault at Bay View Asylum, for the stealing of cadavers, and sentenced to thirty days in jail.

WE LEARN THAT DR. J. B. HAMILTON, who had accepted the position of editor of *The Journal of the American Medical Association*, after a brief experience in the editorial chair, has sent in his resignation, and will continue to hold his position as Surgeon-General of the Marine Hospital Service.

DR. NATHANIEL R. MOSELEY died of heart disease at his rooms in this city, on February 9th. He was about sixty years of age, was graduated at the Pennsylvania University in 1853, and was a member of the County Medical Society, and the Harlem Medical Association. During the War of the Rebellion he was an emergency surgeon in the navy.

DR. R. W. TURNIPSEED, of Hampton, Ga., and ex-member of the Legislature, died suddenly at Atlanta, Ga., on February 10th.

THE CALIFORNIA STATE MEDICAL SOCIETY meets on April 17th.

AN AGGRESSIVE SOCIETY.—We learn from the daily press that the Erie County Medical Society has decided to proceed against all persons practising in Buffalo who are not members of one of the county medical societies. The movement is directly aimed against the various institutes which have been established in the city within the last few years. There is also some talk of proceedings against the Christian science and faith cure practitioners. It is intimated that an effort will be made to change the existing law so that they can be reached. As they give no medicine, they cannot be prosecuted for illegal practice, but the Chairman of the Board of Censors thinks they can be reached another way. He says: "I believe those Christian scientists have an institute here and give diplomas, and obtain much money for them. I think they can be prosecuted under the law regulating colleges, or for obtaining money under false pretences."

UNIVERSITY OF PENNSYLVANIA.—Dr. J. William White has been elected Professor of Clinical Surgery; Dr. John Guiteras, Professor of Pathology and Morbid Anatomy.

DR. JOHANN WAGNER, Emeritus Professor of Internal Medicine at the University of Buda-Pesth, died on January 1st, aged seventy-nine years.

THE GERMAN CONGRESS OF INTERNAL MEDICINE will be held this year in Wiesbaden, on April 15th to 18th, under the presidency of Professor v. Liebermeister. Among the subjects to be discussed are "The Nature and Treatment of Gout" and "The Treatment of Ileus."

THE TRUSTEES OF THE JOHNS HOPKINS HOSPITAL have decided to formally open the hospital on May 1st, and they have confided its organization to President Gilman, of the University. We understand that for one year, at least, President Gilman will reside in the hospital, and exercise a close personal supervision over its executive management.

DR. LEOPOLD WITTELSHÖFER, founder of the *Wiener Medizinische Wochenschrift*, died on January 8th, at the age of seventy-one years. He had withdrawn from the management of the journal only about a week before his death.

DR. NATHAN R. GORTER has sued Robert Garrett for $30,000, for medical attendance on Mr. Garrett when he was abroad, in 1887. Dr. Gorter accompanied the party as far as Berlin, where in May, 1888, he left Mr. Garrett, receiving at this time $1,000 on account.

ARTIFICIAL COCAINE.—Professor Liebreich announces in the *Therapeutische Monatshefte* that he has succeeded in producing cocaine by synthesis.

Reviews and Notices of Books.

THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE RECTUM. By WILLIAM ALLINGHAM, F.R.C.S., England. Edited and Revised by HERBERT WILLIAM ALLINGHAM, Fellow of the Royal College of Surgeons of England. Fifth edition. London: J. A. Churchill. 1888.

MR. ALLINGHAM, JR., has very successfully edited and revised the treatise of his father under the direction of the latter. Several entirely new chapters have been added by the Editor, among which may be mentioned Incontinence of Fæces, Excision of the Rectum, and Inguinal and Lumbar Colotomy. The volume as a whole maintains its previous high reputation as a leading authority on the subject.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Consisting of Original Treatises and of Complete Reproductions in English of Books and Monographs selected from the latest literature of foreign countries. Published monthly.

FOR nearly a score of years past it has been the aim of Messrs. William Wood & Company to supply the medical profession with books at a more moderate price than has obtained among publishers generally, and this without lowering the standard of manufacture of their works. The first outcome of these endeavors on their part was the well known series of books published by them under the general title of "Wood's Library of Standard Medical Authors," unquestionably the most popular and widely sold books of medical literature ever published in any language. After reaching the full number of one hundred volumes, this series has been recently discontinued.

While publishing these books, each of which was a more or less complete and comprehensive treatise upon the subjects of which it treated, they became aware, as indeed, they had before appreciated, that there was a large class of medical literature published abroad and offered by American authors which was practically out of the reach of the profession in this country. Numbers of excellent original papers were continually being written which were too large for journal articles and too small to make profitable books, and which consequently were never published at all, and great numbers of such publications in paper covers abroad, met the same fate in this country for the same reasons. They determined, therefore, as they say in their prospectus of this series, to issue periodically, at monthly intervals, collections of the most valuable of these papers, and basing their estimates upon the remarkable favor accredited to "Wood's Library" they have begun the publication of "Wood's Medical and Surgical Monographs" at a price which casts into the shade their previous efforts in the direction of moderate priced books.

The first volume of this year is before us and is an exceedingly handsome specimen of book-making, clear, legible type, handsome paper, with wide margins and an exceedingly neat cover of heavy leatherette paper. It contains in full the following interesting monographs:

"The Pedigree of Disease," by Jonathan Hutchinson, F.R.S.; "Common Diseases of the Skin," by Robert M. Simon, M.D., and "Varieties and Treatment of Bronchitis," by Dr. Ferrand.

The first named is very proper as an introduction to this series, and should be read by every physician and surgeon, and the following two are of unusual practical value to the general practitioner of medicine.

We notice that the titles of the selections for the succeeding number of the series are printed on the inside of the cover, and we find proposed for the February issue:

"Gonorrhœal Infection in Women," by Dr. W. J. Sinclair; on "Giddiness," by Dr. Thomas Grainger Stewart, and a "Critical Study of the Clinical Value of Albuminuria in Bright's Disease."

The selections for these two issues are remarkably good, and with so wide a range for the collection of valuable material never before published it is fair to assume that the giving and taking of these good things will be mutually appreciated by publishers and readers.

TRANSACTIONS OF THE NINTH ANNUAL MEETING OF THE LARYNGOLOGICAL ASSOCIATION, held in the City of New York, May 26, 27, and 28, 1887.

THE ninth edition of these Transactions is at hand, and we find it bristling with articles of interest to the Laryngologist as well as to the general practitioner.

Nothing adds to the value of scientific research so much as the free and full expression of unbiassed opinion, by which alone disparities of ideas may be reconciled, and this is exemplified in the highest degree in this volume. The article being from the pens of many of our most eminent Laryngologists, with elaborate discussions on each topic, make up a valuable contribution to the history of these diseases.

It would be invidious to attempt a criticism of each separate paper, suffice it to say that almost the entire field of laryngology and rhinology is brought into review, as well as the most approved methods of treatment. Many new instrumental devices are also shown, among which may be mentioned: electric nasal saw and powder-blower, a hæmostatic clamp, and a visiting bag.

THE PRESCRIPTION, THERAPEUTICALLY, PHARMACEUTICALLY, AND GRAMMATICALLY CONSIDERED. By OTTO A. WALL, M.D., Ph.G., Professor of Materia Medica and Botany in the St. Louis College of Pharmacy, Professor of Pharmacy in the Missouri Medical College, Member of the Committee of Revision of the Pharmacopœia of the United States, etc. St. Louis, Mo.: The Aug. Gast Bank Note and Litho. Co. 1888.

THIS is the largest and most complete work on the prescription and prescription writing that has ever appeared in our country. It is, indeed, too large to put in the hands of a student ignorant of Latin (if a faulty preliminary education can ever be corrected in that way), but it is a useful book of reference and contains many practical points in the way of elegance in prescribing, something that physicians are at times prone to ignore. It also treats of weights and measures, the metric as well as the apothecaries', the determination of doses for children, rules for abbreviating, and, indeed, of everything pertaining to accurate and graceful prescription writing.

OPHTHALMIC SURGERY. By ROBERT BRUDENELL CARTER, F.R.C.S., Ophthalmic Surgeon to St. George's Hospital and to the National Hospital for the Paralyzed and Epileptic; and WILLIAM ADAMS FROST, F.R.C.S., Assistant Ophthalmic Surgeon to St. George's Hospital; Assistant Surgeon to the Royal Westminster Ophthalmic Hospital. Illustrated with a chromograph and ninety-one engravings. Pp. 554, 12mo. Philadelphia: Lea Brothers & Co.

THIS is one of a series of clinical manuals for practitioners and students of medicine, but, unlike many so-called "handy-books," it is a compact and complete text-book. The names of the authors are well known to readers of ophthalmic literature; but, at the same time, there is little that is new, and less that is sensational, in this little book. The style of writing is terse and fresh, forcible and piquant, conversational rather than didactic. All through the book there are evidences of a master-hand in surgery as in diction.

The usual preliminary chapters on the anatomy and physiology of the eyeball, and on the examination of the organ, are followed by a careful description of the affections of the tissues, and viewed from before backward. One of the longest chapters is that on the Lenticular System, though but little space is devoted to the revived method of extraction of cataract without iridectomy, now

quite the fashion in France and in the United States. The chapter on Injuries is, perhaps, the most useful for the general practitioner; while that on Amblyopia and Amaurosis will afford pleasure to the connoisseur in ophthalmology, by dint of the peculiar views of the senior author. Mr. Carter states that some writers (obviously referring to his own countrymen) imply that iritis must be either "syphilitic," or "rheumatic;" while, on the other hand, he strongly inveighs against labelling every iritis with the diathesis in which it happens to be found; the danger in the first instance consists in treating only two systemic conditions, while in the second the dangers and the delicate management of iritis are forgotten in hunting about for a proper treatment of the diathesis.

It is with regret that one sees Couper's lachrymal probes carefully put in a wood-cut; these probes are made after Otis' bulbous bougies, and are very large. In 1878 the reviewer saw these large bulbous probes repeatedly used at Moorfields Hospital, with almost always a destruction of the bony lachrymal canal. The region in which they were devised for use by Otis possesses a very different environment from that for which Mrs. Couper devised them.

Fig. 14, p. 84, ticketed Noyes' Needleholder, will be readily recognized as portraying the instrument of Sands. In Fig. 39, p. 233, illustrating the corneal flap in cataract extraction, the letters "A" and "C" should be transposed, else the reader, following the engraving, will enter the cataract-knife at the nasal side, and deliver it at the temporal side of the eyeball. Fig. 45, p. 242, and its context, emphasize the von Graefe bandage, in use twenty years ago; while the light compress and strip of plaster now in vogue in this country are alluded to as a revised novelty of twenty-five years past.

The few pages devoted to sympathetic neurosis and sympathetic ophthalmitis should be read with care.

In the chapter devoted to refractive errors, Mr. Frost has given the following concise rules as to the use of atropine for paralyzing the accommodation: "In the case of adolescents, and adults under thirty, this is, as a rule, unnecessary in myopia, but desirable in hypermetropia and astigmatism; in patients over thirty a mydriatic is only necessary in astigmatism, or when there is any reason to suspect spasm of the ciliary muscle, or when there is great want of control over the muscle, as shown by variations in the answers given in subjective tests.

The usual formulæ seen in English ophthalmic guides find their useful place at the end of this manual.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. TWENTY-FIRST ANNUAL MEETING, JULY 17, 1888; including the Special Meeting of the Society held at Washington, September 18, 1888. Pp. 256. Published for the Society by the Mercury Publishing Co., New Bedford, Mass.

THESE Transactions contain a large amount of otological literature by American writers.

FEEST BUNDEL aan FRANCISCUS CORNELIS DONDERS, op den 27sten Mei, 1888, aangeboden. Door Het Nederlandsch Tijdschrift voor GeneesKunde. 8vo, pp. 546. Amsterdam: F. Van Roosen. 1888.

THIS is a series of forty essays, chiefly on ophthalmic topics, under the editorial leadership of Snellen, read on the occasion of the seventieth birthday of Professor Donders, of Utrecht. The day was devoted to a jubilee in honor of the well-known Donders, of Utrecht. Engelmann, of Utrecht, read a paper on the "Microspectrometer;" Westhoff, of Amsterdam, on "Erythropsia in the Lensless Eye;" Huysdam, of Utrecht, on "Hysterical Mutism;" Snellen, of Utrecht, on "Myosis in Cases of Sclerotomy Performed for Glaucoma;" Landolt, of Paris, read a valuable paper in French on "Verbal Blindness," one case having total right hemiopia, and another having left hemianopsia, with right hemiplegia, the verbal blindness in the latter case being absolute, and accompanied by a loss of mental vision of objects and of memory. Roosenburg, of Gravenhage, contributed two cases of tubercular peritonitis treated by laparotomy. Dooremaal, of Gravenhage, contributed a case of luxation of the eyeball, taking for his thesis the historic case of Dr. Sullivan, of New Hampshire, published in THE MEDICAL RECORD of August 27, 1887.

This jubilee-book of Donders' seventieth birthday is illustrated with seventeen lithographs and colored sketches, illustrating various papers; it marks an era not only in the individual life of the "Master," but also in the progress of the science to which his life has been devoted.

Obituary.

JOHN C. DALTON, M.D.,

NEW YORK.

DR. JOHN CALL DALTON died at his home, in this city, on February 12th, at the age of sixty-four years. He had been sick for some time, suffering chiefly from kidney trouble. An operation made necessary by his complaint was performed recently, but without the result desired.

Dr. Dalton was born in Chelmsford, Mass., February 2, 1825. He evinced a preference for the study of medicine at an early age, and devoted himself assiduously to it in Harvard University, from which institution he was graduated as an M.D. in 1847. He developed a strong liking for literary work, coupled with a taste for physiology, and in 1851 he attained considerable celebrity by an original essay on the "Corpus Luteum," which was written in competition for the annual prize offered by the American Medical Association. The reputation acquired by this effort led to Dr. Dalton's appointment as Professor in the Medical Department of the University of Buffalo, where he remained until 1854, when he accepted a similar professorship in the Vermont Medical College at Woodstock. It is related of him that he was the first professor in the country to teach physiology with illustrations by vivisection.

From Vermont Dr. Dalton removed to the Long Island College Hospital, in 1859, where he remained for two years as Professor of Physiology. He had previously delivered a course of lectures on physiology in the College of Physicians and Surgeons in this city, and in 1855 he was elected Professor of Physiology in the last-named college, a post which he continued to hold until 1883, when he resigned it to accept the presidency of the institution. Dr. Dalton went South with the Seventh Regiment of this city in 1861, and served during the war. In the summer of 1861 he was appointed Brigade Surgeon of Volunteers. He resigned from army service in March, 1864.

Dr. Dalton returned to New York in 1864, and re-entered upon his professional duties in the College of Physicians and Surgeons. He was elected a member of the National Academy of Sciences soon after his return to this city. He at once took an active part in physiological discussions, both at society meetings and in medical publications. He became a member of the New York Academy of Medicine, and served as vice-president of that institution from 1874 to 1877 inclusive. He was also a member of the State Medical Society, the New York Pathological Society, the Medical Journal Association, the Medical Society of New York, and several other organizations.

Among Dr. Dalton's most important physiological publications may be named the following, which were printed in book form: "A Treatise on Human Physiology," "A Treatise on Physiology and Hygiene for Schools, Families, and Colleges," "The Experimental Method of Medicine," "Doctrines of the Circulation," and "Topographical Anatomy of the Brain." Dr. Dalton's contributions to the medical and surgical magazines were very numerous.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-third Annual Meeting, held in the City Hall, Albany, February 5, 6, and 7, 1889.

(Continued from p. 160.)

SECTION IN SURGERY.

TUESDAY, FEBRUARY 5TH.

DR. BERNARD BARTOW, of Buffalo, read a paper entitled

THE DIAGNOSTIC VALUE OF SPINAL ROTATION.

He called attention to the fact that spinal rotation took place in the early stages of spondylitis, because at first the patient voluntarily put himself in a position in which he found the pain less. Irritation was at the bottom of the change in the spine then. Scoliosis was a modified form of rachitis, and really represented a vertebral irritation.

The rotary malposition in spondylitis during the stage when it was due simply to a muscular contraction, and before it became shared in by the bones and ligaments, could be treated successfully. This was not to be done by self-suspension or a plaster-of-Paris jacket put on while so suspended. His method was to make a plaster-of-Paris mould of the body in its existing state, to remodel it to what the normal shape *should have made it*, while still soft, then to make from this in plaster a trunk which represented the normal figure of the patient, and finally on this to model a leather strait-jacket which, when put on the patient, forced him to keep his body in its own normal attitude or form. The patient was to be kept recumbent for the first few days, but after that could go about freely wearing the leather strait-jacket.

A light scoliosis might also be treated thus if we added massage, diet, and suitable exercises. As the strength returned the leather jacket could be punched with holes. This reduced its weight and increased its elasticity. The leather jacket did away with the old plan of having a succession of plaster jackets, as softening, remodelling, and tighter lacing were always possible.

DR. L. A. WEIGEL, of Rochester, had observed the rotary deformity early in spondylitis. If it were really due to irritation, would not simply the recumbent position be as good and better treatment than the jacket?

DR. A. M. PHELPS objected to classing Pott's disease of the spine along with lateral curvature or scoliosis. The latter he regarded as incurable. For the former fixation and absolutely continuous immobilization were necessary, best obtained by the plaster-of-Paris jacket put on with the patient suspended. It could be kept on six months, or even from one to four years. After it was removed there would be need of a light, strong, and flexible brace, and nothing answered better for this than the wooden corset made of thin strips of wood moulded to the body in the shape desired.

DR. BARTOW replied that his leather corset did give complete and continuous fixation, and all the more because it threw the spine into its natural position. Vertical suspension did not correct rotary curvature, but true scoliosis could be cured by the leather jacket.

RECENT ADVANCES IN THE TREATMENT OF HERNIA.

DR. W. B. DE GARMO, in a paper with this title, treated particularly non-strangulated herniæ and recent advances in their treatment. It had become necessary to recognize: *1*. The great variety of forms in which such herniæ might occur. 2. The variety of operations which different prominent surgeons had put forward, of which each surgeon used only that one which he himself had described to the profession. 3. The need of selecting from the different methods the ones which best suited particular and varying cases. The steps in the operation were equally a matter of more or less dispute. Take the question as to whether we should open the sac. Bryant, of London, had said that opening it increased the risk of operation by four times. Others disagreed here. Now if the hernia was small we could assume that there were no changes inside the sac, and return it with the sac unopened. If of any size and not recent, it was to be assumed that adhesions were present. Masses of omentum were to be removed even if reducible. Instead of applying a single ligature after amputation, it was better to spread out the stump of omentum and tie the vessels separately. The stitching of the stump of the sac into the canal was apt to be followed by return of the hernia. The canal must be freed of it. For recent small hernia torsion of the sac was a good measure. If as large as an egg, and easily separated, McCuen's operation was best. For very large hernia Barker's operation was better.

Dr. Pilcher, of Brooklyn; Dr. W. Hailes, Jr., of Albany; Dr. J. P. Creveling, of Auburn; and Dr. Phelps, of Buffalo, discussed details of the treatment.

DR. T. R. POOLEY, of New York, read a paper entitled

OPERATIVE TREATMENT OF AN HYPEROSTOSIS OF THE EXTERNAL AUDITORY CANAL.

The removal of bone in this difficult situation could be done to advantage by drills and trephines operated by the dental engine. A still better means was the electro-osteotome, invented by Dr. J. M. Roberts, of New York, armed with a chuck carrying saws, knives, drills, burrs, and hollow trephines of various sizes. It could be held in the fingers, and was even more delicate than the dental engine. Either of these instruments made the operation less tedious, and avoided the danger of injury of deeper parts by slipping of instruments and pressure when gouges, files, galvano-cautery, or écraseur were used. To remove swelling in the soft tissues following the operation he had found hot water in repeated applications best; soft rubber tubes and catheters only increased it.

DR. C. C. RICE, of New York, urged the importance of avoiding the absorption of septic material. Plugging the meatus was to be avoided. An open wound and constant irrigation gave the best results.

DR. POMEROY thought cases should be selected for operation with great caution. Only those where pain got to be intolerable should be interfered with surgically, seeing the sea of troubles which might follow operation. Iodine and other such drugs were useless. In large exostoses the growth could be quite easily removed by paring it away with a chisel. Inflammation of the middle ear might follow from shock in neighboring parts, even from operation on the inferior turbinated bones.

Dr. Rice and Dr. O. B. Douglas, of New York, had not seen ear affections follow operation on the inferior turbinated except when the posterior nares were plugged; and Dr. J. O. Roe, of Rochester, explained that this only followed when the Eustachian canal was incidentally plugged, hemorrhage into the middle ear sometimes being the direct result.

DR. F. H. POTTER, of Buffalo, read a paper entitled

MEMBRANOUS RHINITIS.

About two per cent. of all his cases of acute rhinitis had been cases of membranous rhinitis. The disease was without assignable cause, and presented no systemic disturbances of any moment. It began as a severe catarrhal rhinitis, but by the third day the discharge became a white tenacious coating, and if forcibly removed the denuded surface was tender and bled easily. It resembled the membrane of diphtheria. Cocaine had no contractile effect till recovery began after a course of three weeks. Other drugs were either harmful or only gave relief or irritation, as when bromides were given. Dry pellets of cotton kept in for five minutes gave slight relief. The drift of opinion was toward a broader conception of the nature of local disease; they were now considered rather as expressions of some constitutional state.

Dr. Rice, of New York, agreed as to the speaker's last conclusion. He had noticed gout, rheumatism, or hay fever in his own cases of membranous rhinitis; also any local causes predisposing to catarrh.

Dr. Roe, of Rochester, believed that all fibrinous exudates into the air-passages and pulmonary structures had a constitutional cause, and one of a similar sort, namely, a pathogenic germ. The result varied with the many various states of individual condition, the location of the infection, and the sort and violence of the germ. The sort of feeding-ground furnished the germ by locally diseased conditions, such as chronic inflammations, did much to determine the effect it would have.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 7, 1889.

A. Jacobi, M.D., afterward A. L. Loomis, M.D., President, in the Chair.

NOMINATIONS FOR TRUSTEE, UNEXPIRED TERM.

Drs. Laurence Johnson and J. E. Janvrin were nominated.

Dr. Castle reported that Dr. Edward Herrick had been made Chairman of the Board of Trustees.

A bust of Dr. Alexander H. Stevens was presented by his daughter, and accepted with thanks.

ADDRESS OF DR. A. JACOBI.

In reviewing the progress of the Academy during his term of office, Dr. Jacobi spoke of the excellent work done by the numerous sections, and named in particular those on the Practice of Medicine, on Surgery, on Obstetrics, and on Pediatrics. For some reason, however, the efficiency of a few sections had remained inferior to that of the rest. The purpose of the Academy was the prevention and cure of disease. "If there be any two sections which are expected to thrive under the shadow of the flag in which that shibboleth is inscribed, it is those of Hygiene and Public Health, and of Materia Medica and therapeutics." A number of the meetings of the former had been marked successes, but the interest in it displayed by the medical profession was not as great as it should be. "How many subjects for its consideration are there? More than bones in the body. Food in infancy, childhood, and advanced age; feeding in hospitals—that means also our hospitals; in prisons—that means our prisons, with the question of work or enforced idleness; drinking-water and its management, with Croton water and Hackensack water supply, Quaker Bridge dam and aqueduct; physical development and work, with the questions involving the bodily and mental future of the Republic, those of male and female and children's factory work, and that of the management of our public schools. No greater service can be rendered the community by any scientific section or society than by offering the knowledge represented in the topics here suggested. Utilizing the summer for the beneficent work of seaside and mountain sanitaria, thus co-operating with the spirit displayed by St. John's Guild, the Children's Aid Society, and others. The questions of sewage and ground-water, the influence of which is but little understood because of the temptation to exaggerate their importance in certain directions; the prevention of infectious diseases, including the topics of disinfection, of vaccination for variola, hydrophobia, and other scourges, and the reduction of mortality in those cases and epidemics after they have started.

"The section on Materia Medica and Therapeutics has not yet been a success. Why that should have been so the members of the section themselves will perhaps not be able to answer. Is it because some of the other sections, particularly those of Internal Medicine, of Pediatrics, and also of Surgery, are in a position to draw on the subjects legitimately belonging to it, but also to them? Or because the name of the section was not, as it might have been, that of 'Therapeutics, including Materia Medica?' Therapeutics—the art of healing—is, as it must be, the final development and aim of all medical service; the crowning edifice of all research is the health and welfare of man, is to prevent and heal disease. Fortunately, sound therapeutics is no longer a pious wish, for it is in therapeutics that the very greatest advance which medicine has made in the last generation has taken place, both through laboratory experimentation and clinical experience. These two—laboratory experimentation and clinical experience—have to co-operate for the elucidation of new facts. The former means experiments on animals, the latter, observation of the sick; but let me say to those who are inclined to be reckless in their enthusiasm, not to experiment on the sick or well. Neither science, nor humanity, nor law permits the exposure of human beings entrusted in their helplessness to public charge to the experimental influence of mineral, vegetable, or parasitic poisons under any consideration or for any purpose, be this even an alleged progress in our knowledge. I speak on this topic with feeling, for it is but a few weeks since I was expected to attend a demonstration of babies who had been wilfully exposed to presumed scarlet-fever poison. But to experiments on animals we owe most of our knowledge on the so-called poisons, on heart stimulants, and on wound infection. Billroth's and Weber's researches in this line, together with the labors of the pharmacologists, have created all that has been called, or is connected with, Listerism, and given rise to all the wonderful achievements of modern surgery. The latter, it is true, has amply repaid for what it received from medicine and pharmacology by the new life it instilled into internal medicine, by local treatment of internal diseases, and those of the nose, larynx, rectum, uterus, bladder, and other organs formerly equally inaccessible to successful management. All of these topics give sufficient work to any number of section meetings, both special and therapeutical.

"In reference to the latter, there are a few facts known to all good observers and therapeutists. For instance: (1) Nature destroys with the same indifference that it heals. It requires assistance. A fractured bone, an empyema, a perityphlitic abscess, a stone in the bladder, a uræmic convulsion, even an attack of asthma, demand interference. Even self-limited diseases require watching and treatment. Diphtheria runs six weeks if quite mild, but a shorter time, it is true, if you let a bad case die by expectant non-treatment; pertussis a few months, if undisturbed in its attacks on the lungs, with the sequelæ of pneumonia or phthisis. Nasal diphtheria is surely fatal unless you disinfect the diseased surfaces. (2) Medication has become more simple and more effective. The big bottles, with contents of one or more dozen ingredients, have made room for shorter prescriptions and alkaloids. At the same time it has become more effective. (3) It has become more local in the same degree that the diagnosis has become so. A diphtheritic stomatitis and pharyngitis demands its chlorate of potassium and tincture of chloride of iron in small but very frequent doses, which develop the general with the local effect. (4) The organic relation of medicaments and morbid changes have been studied more closely; the potassium salts are, therefore, preferable to those of sodium in cases of gouty deposits. (5) Elimination of medicinal agents has been studied. Digitalis is eliminated but slowly, and thus may give rise to cumulative effects, while spartein being both readily absorbed and quickly eliminated, yields a speedy effect and exhibits no cumulation. Iodide of potassium ointments made with fat require days before iodine is found in the urine, while those prepared with lanolin exhibit it within a few hours. (6) It is acknowledged as a principle that the diseased individual must be treated, and not the name of a disease. Those who ask you, How do you treat diphtheria, pneumonia, or typhoid? are getting fewer in number; though it is not quite impossible to hear the pen busy when a

prescription fiend begins to dictate commonplace long-windedness. Thus your medication must often be subsidized with remedies of a different nature, viz., those which stimulate the nervous system by inspiring hope and confidence. Temple dreams, whipping, music, consolation, the sweet breath of young girls, reading and conversation, dancing and reunions, fæces of man and animals and other filth, change of scene, amulets, Hahnemannism potentialities, and other faith-cures, prove to what extent imponderable influences have been brought to bear on the impressible, with more or less imaginary or casual result; and also to what extent a well-informed and thoughtful medical man, interested in the welfare of his patient, can bring to bear on him—mental and moral influences. (7) Nothing is easier than to substantiate the fact that the greatest advances have been made in therapeutics. The last twenty years have not only changed our methods of administration in avoiding the whole plant and adopting only what is needed for special purposes, after investigating the physiological effects of the several ingredients, but also a large number of new substances has been added to the list, and some are most important. It is true iron, mercury, opium, and iodides are left on their old exalted seats, but even the iodides and bromides are not seventy years old. A few instances will show the changes which have taken place. In my own time capital operations were performed without chloroform. But that is perhaps too long ago in our fast-living century to be mentioned at all. But it was as late as November, 1869, that I experimented before the County Medical Society, in the presince of John C. Peters and others, with the first ounce of chloral hydrate which ever reached the country. The salicylates are but fifteen years old, and the large number of alkaloids too many to be mentioned. The derivatives of methan, such as paraldehyd, nitro glycerin, lanolin; those of benzol, as antifebrin, salol, sacchrin, hypnon, naphthalin, and naphthol; the organic bases, cocain, chinolin, kairin, antipyrin, thallin, pyridin, iodol, spartein; the terpenes and camphors of many sorts, such as terebene and terpin, menthol and helenin, have but a brief but victorious existence. (8) Other remedies and methods have been developed in large numbers and rapid succession. Scientific dietetics, gymnastics, hydro- and aerotherapeutics and massage are quite modern; climatotherapeutics has a national society to take charge of it; electrotherapeutics has become one of the household gods of a medical office. Thirty years ago I could not have procured an interrupted current in the city but for the kind services of an enthusiastic Centre Street telegraphic electrician; to-day the improvements in faradic, galvanic, and static apparatuses follow each other rapidly, and the sellers underbid each other.

"The interest awakened by so many new discoveries, inventions, and methods may well occupy a society or section founded for the advancement of therapeutics. It can enhance rapid motion or cut down its exuberances; for progress consists as well in the critical estimation of old, as in the discovery of new, facts. A great many questions are to be answered in regard even to many remedies which appear to have been well studied; for instance, in regard to the *modus operandi* inherent in a number of agents which differ much according to the method of their administration.

"I wish I had the time and capacity of thoroughly going into this subject. If I have but convinced you that I at least believe in therapeutics in general, and also in medicaments in particular, that therapeutics has become scientific since it has been based on physiology, experimentation, and indication, I am satisfied. That, however, does not mean that I believe in prescription-writing as an end, or in *vade mecums*, or all medicine in the vest pocket; or in copying other men's prescriptions for other men's cases from the records of the apothecaries; but it does mean that I look upon therapeutics, including materia medica, as an essential in the medical education of both the student and practitioner, and feel confident that an academic section will confer both honor upon itself and benefit on the profession by nursing it. In the face of all this you find many who shrug their shoulders at internal medicine and therapeutics. Indeed, laymen, and some in the profession who ought to be laymen, punish them with contempt. This is because they have no knowledge of the effect of medicines, of the morbid processes requiring, and the intellectual work of the physician controlling, them. It is particularly the valuation of the latter they are without. It is not the fault of internal medicine that there too few experts after all. It is its complication and difficulty that demands ripe years, hard work, and a keen and powerful intellect before the great physician is made. It is fortunate for mankind that at least modern operative surgery, as based upon the advance of pharmacology, has become an art, and the success of most operations depends upon a few well understood facts and methods easily obtained by an average capacity. Thus a man of thirty, with a well-balanced mind may merit and obtain a great reputation as an eminent operator. Have you heard of a great general practitioner of that age?"

Before concluding his address, Dr. Jacobi paid a glowing tribute to his prececessor and successor in office, and introduced Dr. A. L. Loomis, whose address will be found on page 141.

At the conclusion of his address Dr. Loomis introduced ex-president DR. FORDYCE BARKER, who said he had great difficulty in giving adequate expression to the pleasure he found in being present this evening and in listening to the very able addresses, for it forced upon his mind in strong contrast the difference between now and ten years ago, when he had the honor of giving a valedictory, as illustrating the wonderful growth and improvement in every respect of the Academy. At the close of his remarks Dr. Barker moved a vote of thanks to the retiring President, Dr. Jacobi, for the devotion, zeal, and perfection with which he had performed the duties of presiding officer. The motion was carried unanimously.

DR. LOOMIS said he would expect the members of the sections to do what they could toward making the general meetings interesting, especially by their presence.

Adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 12, 1888.

W. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN S. THACHER presented a heart showing

TRICUSPID STENOSIS.

It was removed from the body of a woman, twenty-nine years of age, who died in St. Luke's Hospital. She had been married six years, and had had two miscarriages but no living children. There was no history of rheumatism, but the patient had had scarlet fever in childhood. She had had leucorrhœa for a number of years. There was no history of syphilis. Five months ago she had some swelling of the feet, and of the left leg and thigh, and three weeks ago the abdomen began to enlarge, and the patient suffered from dyspnœa. The face was congested, but there was no pain about the heart, no palpitation, and no headache. The urine had a specific gravity of 1.010, and contained a trace of albumin, some hyaline and granular casts, and leucocytes. Examination of the heart showed the apex-beat in the fifth intercostal space, four and one-half inches to the left of the median line. The heart's action was irregular. A loud murmur was heard at the apex, but loudest over the mitral area; it was thought to be presystolic, and was not transmitted. There was, also a loud systolic murmur at the base, loudest over the aortic area, and transmitted upward. A few sibilant and sonorous râles were present. The abdominal cavity contained fluid.

Autopsy.—The pericardial, pleural, and peritoneal cavities contained fluid. The left lobe of the liver was twice

the size of the right, and the latter showed some cicatrices, was slightly hobnailed, and seemed to be cirrhotic. The kidneys showed many scars, probably from infarcts; the cortex was thickened, somewhat pale, and the markings were a little indistinct. There was stenosis of the mitral, aortic, and tricuspid valves. The tricuspid would not admit two fingers, was smooth, circular, and slightly funnel-shaped. The mitral admitted one finger, and was very similar in appearance to the tricuspid. The aortic valve would not admit one finger, was nearly circular in shape, and nodular.

Dr. Thacher also presented another specimen, showing a

CONSTRICTION OF THE INTESTINE,

produced by an inflammatory adhesion connecting two portions of the mesentery. The condition was discovered only at the autopsy, as the constriction was not sufficiently tight to give rise to any symptoms during life.

Dr. John C. Peters referred to the frequency of the occurrence of valvular disease of the heart after scarlet fever, which was much greater than was commonly supposed. He had seen many such cases.

Dr. Herman J. Boldt presented a monstrosity consisting of

A DOUBLE-FACED HEAD, WITHOUT TRUNK OR EXTREMITIES.

The specimen was a mass which was expelled from the uterus of a woman, thirty-three years of age, immediately after the birth of her sixth child, and prior to the expulsion of the placenta. In its descent it appeared to the touch as another head, and it was believed by the midwife in attendance that a second child was about to be born. After the delivery of the mass and the placenta, which was unusually large, an examination showed that the child and the monster had membranes and placenta in common, but each had its umbilical cord. The cord from the child had a central attachment to the placenta, while that from the monster had a marginal attachment. The child was a normal one.

The specimen measured three and three-quarter inches in the long diameter, two and three-quarter inches in the transverse diameter, and three inches in the vertical diameter. The weight was not taken. On close inspection the monstrosity had the appearance of a head with two imperfectly developed faces. The faces were on the inferior aspect of the mass, their crowns pointing in opposite directions. In one face two s[illegible] were seen, and were thought to represent the seat of [illegible]e eyes; also a small, pedunculated, fleshy growth, possibly a rudimentary nose. There was neither mouth nor ears. The other face showed one deep slit, oblique in direction, and a shallow sulcus as representatives of the eyes. The nose was a pedunculated piece of flesh, the size of a hazel-nut. The mouth was well marked, with an upper hare-lip and a well-developed lower lip. Starting just above the eyes was a growth of very fine hair, which was not present on the other face.

Examination by transmitted light showed the outlines of cartilaginous plates, which, it may be assumed, were destined to be two frontal and two parietal bones. These plates had dark spots, suggesting centres of ossification. The space between the upper margins of the plates included a greater part of the superior surface of the mass, and, especially in two places, the skin was very thin and transparent. The umbilical cord was on a plane midway between the faces, but a little to one side of a line drawn from nose to nose. In looking over the literature of monstrosities Dr. Boldt had been able to find no record of a similar case. It seemed evident that this one was a double-faced head without a trunk.

Dr. William A. Hume, presented some specimens illustrating a case (see p. 179) of

FRACTURE WITH LOSS OF SUBSTANCE OF THE FRONTAL BONE—ENCEPHALITIS—LATE EPILEPSY—DEATH.

Dr. Mendelson called attention to the appearance of the wound during an epileptic seizure, as described by Dr. Hume, as confirming the old theory of the causation of epilepsy formulated by Schroeder van der Kolk, namely, that the attacks are due to a spasm of the cerebral vessels. In this case both the absence of pulsation and the retraction of the skin covering the opening in the frontal bone clearly pointed to a diminution of the volume of the cranial contents, and the only conceivable way in which the cranial contents could, under the circumstances, be lessened would be by a diminution of the amount of fluid within the cranium, and the most obvious cause for this would lie in a spasm of the cerebral vessels. The case was also interesting from the location of the lesion in the frontal region—a region injury of which is not usually followed by signs of cortical irritation leading to epilepsy.

Dr. Hume said that the microscopical examination of the brain had not yet been completed, and it was possible that a degenerative process would be found extending back and involving the motor tracts. Still the epilepsy might have been simply reflex in character occasioned by the irritation from the extensive lesion in the anterior lobe.

Dr. Eugene Hodenpyl presented specimens of

CARCINOMA OF THE STOMACH AND SUPRARENAL CAPSULES.

In the stomach the lesion was at the pyloric extremity. The regions where the suprarenal bodies should be found were occupied by two masses of friable tissue, and there were no evidences whatever of the proper substance of the adrenals. Examination under the microscope showed the new growths to be alveolar carcinomata.

Dr. Hodenpyl also showed sections of the suprarenal bodies from a case of

ADDISON'S DISEASE.

The patient was a woman, twenty-four years of age, and was born in Ceylon of English parents. Her father was living and healthy. The mother died at the age of seventy-three years. The family, on both sides, were pronounced brunettes, and the mother, especially, had an unusually dark complexion. It was often noticed that during periods of illness, even of a trivial nature, the patient's skin became much browner than at other times. There was no history of tuberculosis. During infancy and up to the age of fifteen years the patient had always been healthy. At this time she had a severe attack of sickness, lasting one month, the nature of which is obscure. The father states that the trouble began in "a gathering in the forefinger," followed by severe constitutional symptoms, delirium, fever, etc. About five years ago the parents noticed that the patient was failing in health. She began to lose flesh, strength, and appetite. She became stupid and apathetic. Her skin gradually became darker in color. She also developed attacks characterized by intense headache, nausea, and vomiting, diarrhœa alternating with constipation, great pain and tenderness over the abdomen, and occasionally delirium, lasting three or four days. These attacks varied a good deal as regards duration and severity, but they were more frequent during the past two years. The patient was admitted into the hospital suffering from one of her "bilious attacks." She was exceedingly dull and apathetic, and could give no good account of herself. On physical examination the skin was seen to be of a very dark brown color. The mucous membranes were considerably pigmented. Examination of the heart and lungs gave negative results. Considerable pain and tenderness existed over the abdomen. The spleen was not enlarged. The urine contained a trace of albumin. Pulse, 90; respiration, 20; temperature, 100.2°. She had headache, nausea, vomiting, irregular bowels, and occasionally mild delirium. While in the hospital the patient's skin was at times of a decidedly browner hue than at others, and it varied from day to day, apparently without regard to her

general condition. She finally passed into the "typhoid state," the stupor developing into coma, and she died April 29, 1888.

Autopsy.—The body was well nourished, the rigor mortis well marked. The skin over the whole body, especially the lower half, was of a dark, chocolate-brown color, the nipples and labia being almost black. The mucous membrane of the mouth, nose, and vagina was pigmented. The left lung was moderately œdematous, the right, firmly adherent to the chest-wall and diaphragm, congested and œdematous. In the apex there was a single small calcified nodule. The bronchial glands were not enlarged. The heart was small, flabby, and the muscle pale; the mitral valve was slightly thickened. The stomach was normal. The small intestines contained a number of congested and pigmented areas. The large intestine was normal. The liver was adherent to the surrounding parts, being attached by numerous dense and firm adhesions; the color was dark, and the cut surface smooth. The spleen was of normal size, very firmly adherent, soft, and contained three very small calcified nodules. The pancreas was normal. The suprarenals of both sides were enlarged to about three times their normal size. They were of stony hardness, and the cut surface showed that the medullary portion had been entirely converted into a cheesy and calcareous mass, the cortical portion being replaced by a pale grayish, semi-translucent material. The kidneys were rather large and firm, and of dark color, with the capsule adherent in places. The cortex was not thickened, and the markings were fairly distinct. The mesenteric glands were not enlarged. The thyroid was rather small and dense. The thymus was large, and projected as far as the third rib. Lying on either side and behind the trachea were two or three enlarged cervical lymph nodes which were entirely converted into cheesy and calcific material. The brain was normal.

Microscopical examination: Sections from the suprarenals and cervical lymph nodes, when stained for tubercle bacilli, gave negative results, although the lesion was evidently a tubercular one in an advanced stage. In and around the blood-vessels of the kidney were collections of small spheroidal cells, and scattered about were masses of small round cells between the tubules. The spleen showed the lesions of congestion and hyperplasia. The liver was a little fatty. In the thyroid body, and principally around the periphery of the lobules, were here and there masses of small round cells, in places forming a zone of cells around a lobule; in other places they simply occurred as irregular masses. Moreover, there seemed to be an irregular infiltration of small cells into some of the lobules.

As regards the source of infection in this case, it is possible that the "gathering" in the finger might have been tubercular. The small round cells in the thyroid were very abundant. The speaker said that he had not made up his mind whether they were leucocytes or lymphoid cells. If they were the latter, the case would be an uncommon one, for lymphoid tissue was very seldom found in young people. In reply to a question whether tubercle bacilli had been found in Addison's disease, he said that Osler had discovered them in two cases, but that they are not ordinarily found in this disease.

Dr. J. C. Peters said that the first case of Addison's disease described in this country was presented at a meeting of this Society by Dr. John T. Metcalfe.

Dr. Henry N. Heineman, in response to a request to give a definition of the term "Addison's disease," after observing incidentally that Addison's disease seemed to be a much more common affection abroad than in this country, said that the affection is one in which certain phenomena, consisting in nervous symptoms and a pigmented skin, are associated with changes in the suprarenal bodies. These changes, however, are of the most varied character, and it is as yet impossible to give any exact definition of the disease, for the subject has not yet been sufficiently worked up to admit of such a definition.

Dr. John S. Ely presented two enormously enlarged

CYSTIC KIDNEYS

removed from a hog at the slaughter-house. There was hardly any kidney tissue remaining, the organs being made up almost entirely of cysts, which seemed to be retention-cysts. There was a very abundant growth of connective tissue.

Dr. Mendelson remarked that the specimens were interesting in connection with the question of gout in hogs. In a case of such gout described by him about a year ago, he had been able to show that this form bore a very close resemblance anatomically to the urate gout of man. The kidneys just presented showed that chronic interstitial nephritis—the "gouty kidney"—of human beings, one of the less obviously gouty lesions, was also represented in the hog. The speaker also dwelt upon the importance of the study of comparative pathology, and urged members, whenever possible, to bring specimens illustrating diseases of the lower animals.

Dr. Mary A. Dixon Jones presented a specimen of

INTRAMURAL MYOMA OF THE UTERUS,

removed from a patient forty-four years old; married twenty-four years; no children. The tumor lay low in the pelvis, and made considerable pressure upon the bladder and rectum. It commenced at the internal os, completely occluding the uterine canal. There was also a subperitoneal fibroid, the size of an infant's head. Both tumors were removed by suprapubic hysterectomy, the stump removed per vaginam, as in kolpo-hysterectomy. The operation was successful, but the patient afterward succumbed to an old kidney trouble, complicated with heart disease. The microscopical examination of the uterine appendages showed long-existing disease.

A second specimen was one of

FIBRO-CYSTIC TUMOR OF THE BROAD LIGAMENT.

The patient was forty-eight years old; married twice; no children. Menstruation began at fourteen, accompanied, as she said, by terrific pain, which year by year became more and more severe. The patient had to have recourse to morphine. For years she was treated for uterine disease, without results. Probably disease of the ovaries commenced in early menstrual life. The growth had been observed for eight or nine years. When she came under observation in May, 1888, it was about nine inches in diameter, and the lower part was tightly wedged into the pelvis, pushing the uterus to the right. She entered the Woman's Hospital of Brooklyn May 30, 1888, and the tumor was removed three days later. It had an immense pedicle, with a great predominance of fibrous tissue. The patient made an excellent recovery. Microscopical examination of the tubes showed a very unusual condition, viz., hyperplasia of the mucosa, the mucosa being changed to fibrous connective tissue, a new formation of blood-vessels, and a new growth of epithelia.

Dr. Jones then exhibited a number of

MICROSCOPICAL SECTIONS OF DISEASED OVARIES.

Patient was forty years of age, feeble and emaciated. Nine years previously she had consulted an eminent specialist, who diagnosed her case inflammation of the ovaries. The disease continued to increase, the left ovary was changed to dense fibrous connective or cicatricial tissue, the outcome of chronic oöphoritis; some portions were calcified, containing globular deposits of lime salts, and between them angular protoplasmic bodies like bone corpuscles. The right ovary was much enlarged, and most of it occupied by a fibroid growth or tumor, while in other portions of the ovary there were a number of small nodular fibromata, in the neighborhood of which the blood-vessels were much enlarged, probably by pressure. In the same ovary was a form of degeneration which Dr. Jones had not elsewhere seen described. In May, 1887, she presented to this Society a microscopical section, showing this formation. The patient had since emaciated and suffered much pain.

Two years before, June, 1885, the speaker had removed diseased ovaries from a woman who had been an invalid for fifteen years. In these ovaries there was the same kind of formation. The case was published in THE MEDICAL RECORD, August, 1886, and the growth pronounced to be sarcoma. In August, 1887, she sent a microscopical specimen of this growth to Waldeyer, of Berlin. He replied October 18, 1887, that it was carcinoma. But from drawings made the summer previous, Dr. Jones could see that in the growth there were tracts of nucleated protoplasmic bodies, which nucleated bodies were coarsely granular, sometimes elongated, sometimes round, or forming an irregular network. When they were round and even they gave very much the appearance of round-cell sarcoma; but in some places these elongated protoplasmic bodies seemed to melt into each other, forming canals, in which were hæmatoblasts and the shadows of blood-corpuscles. Again, many of the protoplasmic bodies were like cut sections of blood-vessels, filled with blood-corpuscles, and in other portions there were completely formed blood-vessels. So the growth is a new formation of blood-vessels. But we do not know why an ovary should degenerate into this structure, or what is its pathological significance.

CANCER OF THE OVARY.

On March 28th, Dr. Jones reported to the Society the removal of a tumor from the floor of the pelvis, which was bound down by firm and strong adhesions, completely grown to the part. Before the operation the diagnosis was made of an enlarged left ovary, caused probably by an abscess. The patient had suffered for many years, but not more than many have suffered from apparently similar conditions. The removal was very difficult, but the patient made an excellent recovery from the operation, had a good appetite, and was apparently in excellent health. During the last two months, however, she has had an increase of pain, and an enlargement at the seat of the old tumor. A microscopical examination of the portion of the ovary that was adherent to the floor of the pelvis shows it to have been a cancer of the most malignant type. The little connective tissue around the cancer nests were infiltrated with the cancer. The tubes were also infiltrated.

DR. HENRY P. LOOMIS presented a specimen of

CYLINDRICAL-CELLED EPITHELIOMA OF THE STOMACH, WITH EXCESSIVE DILATATION.

The patient, a male, forty-eight years of age, was admitted to Bellevue Hospital November 26th. His family history was unknown; he was grossly intemperate, had syphilis as a young man, and gave the evidences of tertiary manifestations. The patient could give no definite statement as to how long he had been ill, but thought he first began to vomit his food about a year ago. He said "he would go for several days eating and then gradually feel more and more loaded up, and finally vomit a quart or more." After unloading his stomach he would have a good appetite and would eat heartily again, but gradually his appetite would fail, and then he would feel an oppression in the epigastrium and would vomit. This was repeated constantly during the past year. Patient suffered a gnawing pain in his epigastrium for the past six months, which gradually became paroxysmal and has never become constant, he all the time growing weaker and losing flesh. Has never vomited blood, but only a slimy, greenish, sour-smelling fluid. During the past few weeks he failed rapidly; had complete anorexia during and after his attacks of vomiting. Bowels have been regular. During the whole of his illness he was anæmic and emaciated. Pulse rapid and feeble. Physical examination of the chest gave negative results. Liver dulness extended from the fifth rib to one and a-half inch below the free borders of the ribs. Abdomen very much retracted. Outline of the stomach was clearly defined, its upper border extended as high as the ensiform cartilage, while the lower border reached three inches below the umbilicus; the pyloric extremity of the stomach extended into the right lumbar region as far as the free border of the ribs; the cardiac end of the organ was in the left lumbar region. No tumor could be detected in the abdomen. The stomach was siphoned, and a large quantity of a slimy, black, sour-smelling fluid was withdrawn, and it was washed out with warm water and a pint of milk was then introduced.

The patient was comfortable for twenty-four hours, and then the washing-out had to be repeated. In spite of nutritive enemas and the introduction of milk into the stomach, the patient died within ten days from asthenia. The test for free hydrochloric acid was employed, with negative results.

Autopsy, made twenty-four hours after death: Lungs showed pulmonary œdema and congestion. Heart, normal. Liver, fatty infiltration with passive congestion. Kidneys, normal. Stomach measured eight inches along its lesser curvature, and twenty-three inches along its greater. It was greatly distended, and could contain about two and a-half quarts of fluid. The opening into the duodenum was so small that with difficulty a medium-sized probe could be passed. At its pyloric extremity was a tumor, circular in form and about an inch and a half in diameter, raised above the mucous membrane of the stomach less than a quarter of an inch. It was of dense consistency and with no portion of its surface eroded, and showed the microscopical elements of epithelioma. Intestines: all the small intestines were very much atrophied, and presented a pale, anæmic appearance.

The following are the interesting points of the case: There were none of the usual symptoms of cancer during life, for the case had been examined by a number of competent gentlemen who had not even suggested the possibility of cancer. No tumor was at any time detected, nor was the growth found at the autopsy sufficient to give signs of a tumor during life. The only symptom which suggested obstruction at the pylorus was the evidence of stomach dilatation. A microscopical examination showed it not to have been the ordinary variety of cancer met with at that situation.

DR. W. P. NORTHRUP presented a case of

EXTENSIVE INTERLOBULAR EMPHYSEMA,

with broncho-pneumonia, in a child aged five months. Patient was sick five days with signs of pneumonia; temperature 104° F. (rectum), and had a discharge from the nose two days before death.

There had been no whooping-cough, no eruptive disease before or with the last sickness, and no pseudo-membrane was visible. Had been accepted a strong and well child. On autopsy the body was found to be well nourished. A small abscess, located on the rib at its junction with the fourth costal cartilage of the right side, was discovered on separating the muscles from the bony wall. This was localized purely in the rib, affecting neither the pleura nor muscles. Pharynx contained moderate amount of mucopus, a thin pellicle of fibrino-pus, and was somewhat congested upon tonsils and elsewhere. Larynx had upon its surface a thin pellicle of fibrin and pus, which showed under the microscope reticulated fibrin containing in its meshes small round cells. This extended as far down as the bifurcation of the trachea. Right lung: broncho-pneumonia of posterior portion of all lobes and extensive interlobular emphysema of upper; large air-sacs, of capacity of a drachm, wedge-shaped, from wide base at margin of the lung, growing smaller to the root. Left lung: broncho-pneumonia of the lower posterior portion. Other organs normal.

Dr. Northrup presented a case very similar to the present at the last meeting of the Society, and thought the second case would be of interest, taken in connection with the first. In neither case was there any convulsive muscular action to account for the lesion, nor any symptom of obstruction in the air-passages.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE AT THE PATHOLOGICAL SOCIETY ON THE MORBID ANATOMY AND PATHOLOGY OF CHRONIC ALCOHOLISM: SPEECHES BY DRS. HADDEN, ORMEROD, ISAMBARD OWEN, BERNARD O'CONNOR, AND D. R. PEARSON; DR. PAYNE'S REPLY—AN IMPORTANT SUPPLEMENT TO THE OPERATION OF INGUINAL COLOTOMY—CLINICAL INSTRUCTION ON FEVERS.

LONDON, January 21, 1889.

THE special debate at the Pathological Society on the morbid anatomy and pathology of chronic alcoholism was resumed on Tuesday evening last, and brought to a conclusion. Dr. Hadden was the first speaker on the resumption of the debate. He referred to six fatal cases of alcoholic paralysis which had come under his own observation. The spinal cord was normal in all. In five cases the nerves were examined, and found to be degenerated; the changes were more advanced in the smaller nerves. Phthisis was present in four of the cases, miliary tubercles in the lungs in one, softening broncho-pneumonia in one. There was marked cirrhosis of the liver in four out of his six cases and advanced fatty change in the remaining two. He had seen various trophic lesions in cases of alcoholic paralysis. As regarded the influence of alcohol on the kidneys, he had examined between fifty and sixty cases of cirrhosis of the liver, and found interstitial change present in the kidneys in one-third; in only half of this number was the change at all noteworthy. In about one-fifth of these cases of cirrhosis lung-changes existed. It was interesting to note that of fifty cases of granular kidney cirrhosis of the liver was present only once, but in a few there was fatty change.

Dr. Ormerod referred to the sections he had shown from a case of typical alcoholic paralysis. The specimens showed breaking up of the myelin and overgrowth of the endoneurium; some of the axis-cylinders were destroyed. The cause of death was phthisis. He also referred to an alcoholic disease of the nervous system described by Wernicke and Thomsen and to a case of alcoholic ophthalmoplegia described by Dr. Suckling.

Dr. Isambard Owen then related the results arrived at by the Collective Investigation Committee of the British Medical Association on the subject of intemperance. An idea had got abroad that the committee stated that total abstinence was a very bad thing and that total abstainers had a relatively earlier mortality than drunkards. Dr. Owen said he emphatically denied this on behalf of the committee; they had intentionally not announced any definite conclusions. Referring to the data on which the committee based their report, he said they showed that the temperate had an average of sixty-two years of life, the intemperate of fifty-two years, and total abstainers showed an average of only fifty-one years. The lowness of the latter rate was, however, due to the fact that a great majority of total abstainers were young people; total abstainers above forty had at least four years expectation of life longer than the habitually intemperate. The committee also found that the earlier mortality of the habitually intemperate was due to specially alcoholic diseases, such as cirrhosis of the liver, and gout. There was a larger number of the intemperate with kidney diseases than the temperate, but that was shown to be due to gout rather than directly to alcohol.

Dr. Bernard O'Connor asked as to the *modus operandi* of the irritation caused by alcohol. Referring to the fact that different lesions were produced by different alcoholic liquors, he said that among hop-pickers in Kent delirium tremens was more frequently produced by beer than by spirits. He thought gout was produced by other things in beer than alcohol.

Dr. D. R. Pearson then spoke, and said that the liver, being the organ which most directly dealt with alcohol, was found in practice to be first and most largely affected by it. That the lungs and kidneys were more rarely and less affected by it was probably to be accounted for by their office as excretory organs, and by the fact that in the lungs the alcohol met with dilution in the form of watery vapor, and in the kidneys by more direct dilution. The coats of the stomach were probably the only tissues which could be proved to suffer by the direct toxic action of alcohol. Dr. Pearson then discussed in detail the action of alcohol upon the pulmonary tissue.

Dr. Payne then replied. He thought the Society might be congratulated upon the issue of the discussion, but they had not received so much information as he had hoped upon certain points; viz., the condition of the tongue, of the gastric and intestinal membrane, and of the skin in chronic alcoholism. Nor had the discussion brought to light any distinctly new facts with regard to the effect of alcohol on the kidneys. The interest of the subject remained concentrated, as before, chiefly on two points, viz., the effect of alcoholism on the liver and its effect on the nervous system. After discussing at considerable length the facts and opinions put forward by the various speakers, Dr. Payne said the general outcome of the discussion seemed to be that structural, as distinguished from functional, disturbances due to alcohol used in excess had more importance than had been assigned to them, and that the action of alcohol on the tissues was a toxic one and had more resemblance to the action of mineral poisons than we had been accustomed to think. He would venture to draw the corollary that these injurious effects were produced in a preponderating degree, or almost entirely, by concentrated forms of alcoholic drinks. If he were right, the practical conclusion would be that the injuriousness of a large quantity of alcohol was almost in direct proportion to the degree of concentration in which it was ingested.

At the last meeting of the Medical Society of London Mr. Herbert Allingham read a paper in which he suggested an important supplement to the operation of inguinal colotomy. He had observed in several of his cases of inguinal colotomy that the patients afterward suffered from a distressing procidentia of the intestine through the inguinal opening. He had at first imagined that this arose from too large an incision, but did not find such to be the case. He at length came to the conclusion that procidentia occurred only when the sigmoid mesentery was of considerable length. He had devised the following method of operating in such cases: He pulled out through the wound all the intestine that would possibly come forth, and, allowing these portions of the intestine to rest upon the abdomen, then sutured them. In from twelve hours to three days afterward he entirely removed all these pieces of intestine, first having applied a clamp about an inch from the wound to prevent the intestine from slipping. Experience taught him that the clamp must be spiked, and must possess a firm and tenacious grip, otherwise severe hemorrhage might ensue. The clamp should be allowed to remain on for twelve hours—indeed, so long as any slackening of it produced bleeding. Pain occurred when cutting through the mesentery, but not when dealing with the intestine proper.

With all our boasted modern improvements in medical education, there is a danger of its becoming unpractical. Even as regards clinical work there is always a tendency to pay undue attention to rare and interesting cases and to somewhat neglect the study of the more common ailments, which, however, will hereafter occupy so large a proportion of a general practitioner's time and attention. By excluding cases of fever, our large hospitals really encourage ignorance about them. Students have consequently to gain their real experience of such diseases as measles and scarlet fever, after leaving the hospital. I have, indeed, known a case in which a student never met with a case of measles at all during his student career,

but encountered his first case after becoming qualified. Under the old apprenticeship system—the extinction of which is regretted by many practitioners—such an incident would have been impossible of occurrence. Under these circumstances, it is gratifying to find that it is proposed to utilize for teaching purposes the fever hospitals of the Metropolitan Asylums Board. The danger of infection is, however, not to be disregarded in visiting such institutions. Should the proposition be carried out, it is to be hoped that the students attending will be required to use every reasonable precaution against infection. It would, indeed, be well to admit at first only those already protected by previous attacks.

THE TWENTY-FIVE BEST DRUGS.

To the Editor of The Medical Record.

Sir: In the editorial on "The Best Twenty-five Drugs," in your issue of January 19, 1889, you invite correspondence from physicians in general practice.

I believe in medicine, as in letters, that the end desired can be equally well attained by different means. The practice of medicine is not an exact science, and specifics among drugs are rare, if, indeed, any at all exist. It will do us all good, however, to learn with what preparations our fellow-practitioners alleviate and cure diseases. Your list is an excellent one, but I should omit from it ether, aloes, chloral, and nitrites, and substitute gelsemium, rhubarb, bismuth, and glycerine. I should also want "bicarbonate of potash" changed to read "potash," regarding the nitrate, chlorate, acetate, and hydrate of as much, if not more value than the bicarbonate.

If your order is to be regarded as that of merit or value I should want some changes made. But I do not so understand your intention, so I follow the same order. My list of the twenty-five best drugs—agreeing with your editorial that many more are often used to advantage—is: 1, Opium; 2, mercury; 3, iodides; 4, quinine; 5, chloroform; 6, gelsemium; 7, sulphate of magnesia; 8, salicylic acid; 9, rhubarb; 10, alcohol; 11, bromides; 12, iron; 13, bismuth; 14, castor-oil; 15, digitalis; 16, arsenic; 17, colchicum; 18, ipecac; 19, aconite; 20, strychnia; 21, cocaine; 22, ergot; 23, potash; 24, mineral acids; 25, glycerine.

Very truly yours,
Spencer M. Free, M.D.

Beechtree, Pa., January 29, 1889.

AN INCONVENIENCE OF THE METRIC SYSTEM.

To the Editor of The Medical Record.

Sir: In the discussions of the merits of the decimal system of weights and measures which have come under my notice I have not observed any mention of one drawback which I have found in my own experience, and have noticed sufficiently often in the writings of others to lead me to think my mind is not altogether peculiar in that respect—I refer to a tendency to confuse the different denominations—centigrammes and milligrammes, centimetres and millimetres—which I have not observed in the use of drachms and grains, feet and inches. For example, I would refer to the very interesting article of Dana on "Cranio-cerebral Topography," in your issue of January 12th. On page 35 he gives the situation of the upper end of the fissure of Rolando in children as "30 ctm. behind the bregma in one case, 38 and 40 in two others," which would be equal to 11.8 inches in the first case, and 15.7 in the last—measurements which would imply a pretty high degree of hydrocephalus. He gives the same measurement in adults (p. 37) from 25 to 30 mm., and then, in the following paragraphs, goes on to quote Féré to the effect that "in imbeciles with arrested development of the fore brain the upper end is nearer the bregma, being from 30 to 32 ctm. behind it," and makes Fouillehouze say that in children the same measurement is 30 to 35 ctm. I have not verified the references, but if they are correct it would show that the evil I deplore is more wide-spread than I supposed.

Again, p. 40, he informs us that the optic thalamus and corpus striatum lie about 35 ctm. (14 inches) below the surface of the brain.

These errors, as they stand, are probably harmless, but if the author should make analogous mistakes with equal frequency in his prescribing, it would be for the interest of his patients that he should have a careful apothecary.

Decimal.

Little Rock, Ark., January 17, 1889.

New Instruments.

A NEW INSTRUMENT FOR TRACHEOTOMY.

By Edgar Holden, M.D.,
Newark, N. J.

This instrument was designed to add to our resources for relief in occlusion of the larynx, and possibly to take the

place of tracheotomy and intubation in some cases, particularly where interference must be immediate. The drawings submitted are of the full size of the instrument.

It consists, 1st, of a curved pair of smooth blades about one inch in length, and one-sixth to one-eighth in width, fringed at the base with flaring lower ends and

lever-like projections; 2d, of a handle with curved, trocar-like point, on which the blades fit for introduction.

The perforation is made through the crico-thyroid space, the hinged blades (or divulsor) are detached, the trocar withdrawn and the closed blades slipped upward between the vocal cords, separated and held apart by a perforated bar, which drops or can be pressed downward for the purpose. The operation can be almost instantaneous, almost bloodless, and the instrument withdrawn and replaced at will.

The opening into the air-passages is but two lines in width, and is closed by the divulsor. The parts remaining outside permit a view of the edges of the wound.

The drawings will perhaps explain the device without further description.

It is, perhaps, not applicable to infants, in whom the crico-thyroid space has not developed so as to be readily felt by the finger.

P.S.—The instrument is made by John Reynders & Co., New York.

Army and Navy News.

Official List of Changes in the Stations ana Duties of Officers serving in the Medical Department, United States Army, from February 3 to February 9, 1889.

BAXTER, JEDEDIAH H., Colonel and Chief Medical Purveyor. By direction of the Secretary of War, to proceed to New York City on public business connected with the Medical Department, and on completion thereof to return to his station in this city. Par. 17, S. O. 30, A. G. O., Washington, February 5, 1889.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the President, in pursuance of the authority contained in the provisions of the act of Congress approved March 3, 1887, "making appropriations for sundry civil expenses of the Government," etc., relating to the methods of preventing the spread of epidemic diseases, to proceed to the Island of Cuba for the purpose named in the letter of the President addressed to the Secretary of War, April 17, 1888, and upon completion of this duty to return to his proper station and submit his report to the President. Par. 16, S. O. 30, A. G. O., Washington, February 5, 1889.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the Secretary of War, is relieved from duty as attending surgeon and examiner of recruits at Baltimore, Md., to enable him to comply with the requirements of paragraph 16, S. O. No. 30, of the 5th instant. Par. 4, S. O. 31, A. G. O., Washington, February 6, 1889.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor, and HEIZMANN, CHARLES L., Major and Surgeon. By direction of the President, detailed as members of the Army Retiring Board at San Antonio, Tex., convened by War Department order dated January 16, 1888, published in S. O. No. 12, January 16, 1888, from Headquarters of the Army, vice Lieutenant-Colonel Edward P. Vallum and Major Francis L. Town, hereby relieved. Par. 15, S. O. No. 28, A. G. O., Washington, February 2, 1889.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon. By direction of the Secretary of War, having appeared before the Army Retiring Board at Fort Leavenworth, Kan., in compliance with paragraph 1, S. O. No. 4, January 5, 1889, from this office, will repair to this city to await action on the proceedings in his case. Par. 12, S. O. 32, A. G. O., Washington, D. C., February 7, 1889.

KILBOURNE, HENRY S., Captain and Assistant Surgeon. Having complied with par. 2, S. O. No. 6, Department of the Columbia, will return to his station, Vancouver Barracks, W. T. Par. 1, S. O. 9, Headquarters Division of the Pacific, San Francisco, Cal., February 2, 1889.

THEARNS, EDGAR A., Captain and Assistant Surgeon, Fort Snelling, Minn., will proceed without delay to Fort Pembina, Dak., and report to commanding officer of that post for temporary duty. Par. 3, S. O. 12, Headquarters Department of Dakota, St. Paul, Minn., January 31, 1889.

LA GARDE, LOUIS A., Captain and Assistant Surgeon. By direction of the Secretary of War, leave of absence granted in S. O. No. 290, December 13, 1888, from this office, is extended three months. Par. 2, S. O. 31, A. G. O., Washington, February 6, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending February 9, 1889.

HALL, J. H., Passed Assistant Surgeon. Ordered to Naval Hospital, Washington, D. C.

ECKSTEIN, H. C., Surgeon. Detached from U. S. S. Adams and wait orders.

DIXON, W. S., Surgeon. Detached from special duty at Baltimore, Md., and to the U. S. S. Boston.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 9, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	0
Scarlet fever	332	55
Cerebro-spinal meningitis	5	2
Measles	271	23
Diphtheria	192	50
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

BACTERIAL ORIGIN OF YELLOW FEVER.—Dr. Paul Gibier, of Paris, N. Y., referring to his recent paper before the Academy of Medicine, writes: "I have not said that 'it was my opinion that if yellow fever was a bacterial disease, it would not be impossible to *confine* it to the inhabitants of countries exposed to the epidemic.' At first, I did not doubt at all of the bacterial nature of yellow fever, and I said that 'it would not be impossible *to protect* against yellow fever,' etc. . . I shall say more, and will avail of your courteous hospitality to tell you that from experiments I have performed on the bacillus isolated by me in Havana and in Jacksonville, I am positive that the germ of yellow fever could be easily destroyed at its sources."

DURATION OF INCUBATION AND CONTAGIOUSNESS.—The following circular has been issued by the Clinical Society of London: "Ten years ago the Clinical Society of London appointed a Committee to investigate the periods of incubation and of contagiousness of the commoner communicable diseases. A certain amount of valuable material was received, but it was thought desirable to defer the presentation of a report until further experience was available. The Society has now determined to gather additional information with a view to the preparation of an early report on the subject, and for this purpose has reconstituted the Committee. The Committee is desirous of obtaining particulars of cases which throw light upon the periods of incubation and contagiousness of the below-mentioned diseases, and will be grateful for notes of any cases where the facts can be ascertained with sufficient precision to afford grounds for conclusions. It is thought that gentlemen practising at a distance from large centres of population, and especially those engaged in the Public Health Service, or associated with schools, would be able

to supply information of the kind required. A single case in which the dates of exposure to infection and the appearance of the first symptom can be accurately fixed, especially where the exposure has been limited in duration, would be highly valued. The following diseases are included within the scope of the inquiry: Variola, varicella, measles, German measles, scarlet fever, typhus, relapsing fever, whooping-cough, diphtheria, enteric fever, cholera, erysipelas, mumps, infectious sore-throat. The Committee consists of Dr. W. H. Broadbent, Dr. George Buchanan, Dr. Cayley, Dr. Thomas Barlow, Dr. Alfred Hill, Dr. Isambard Owen, Dr. Thorne Thorne, Dr. Alder Smith, and Mr. R. W. Parker with Mr. Shirley Murphy, 41 Queen Anne Street, and Dr. Dawson Williams, 25 Old Burlington Street, W., as Honorary Secretaries, to one of whom communications should be addressed. W. H. Broadbent, *Chairman of Committee.*—Clinical Society of London, January, 1889. P. S.—An early reply would facilitate the work of the Committee."

Concerning Electrical Instruments Used in the United States.—Dr. A. de Watteville, editor of *Brain* (London, England), writes: "May I appeal to your generosity for a corner of your valuable space? The object is, I am afraid, rather a personal one; but American courtesy to foreigners is too well known for me to apprehend a rebuff. The matter is plainly this: I wish to appeal to those of your readers interested in medical electricity for a few hints regarding the various instruments made and used in the States, which give satisfaction, and in what particular direction; what firms stand highest in the esteem of professional experts; in what particulars the several American instruments surpass, or are inferior to, those of European make. I do not, of course, expect more than brief hints on the part of those of my professional brethren willing to assist me; and every statement will be treated as strictly confidential. Reprints of articles and illustrated catalogues of the leading firms will be also gladly received."

Polyandry.—The form of polygamy with which we are most familiar is that where the husband has more wives than one. Among some nations, in a more or less uncivilized state, it is, indeed, as much the custom as monogamy is in civilized countries. Another form of polygamy, where the woman has more than one husband, called polyandry, exists in several parts of the world widely separated from each other. Thus, it has been found among the people inhabiting the centre of Ceylon; among the Todas and Nairs of Southern India; among the Iroquois Indians of America; among the aboriginal inhabitants of Tasmania before they became extinct; and it is found to be especially prevalent among the inhabitants of Thibet. As practised in the latter country, it seems to differ from the custom in other countries where it occurs, in that the husbands are brothers or nearly related kinsmen, so that the woman becomes the wife of the whole family. Instances, where as many as five or six brothers have one wife in common to all of them, have been recorded; but in most cases a woman has not more than two or three husbands. The choice of a wife for the family is the right of the eldest brother, whose marriage contract involves contracts with all his brothers. The children are regarded as the common property of the house, and all the husbands are treated as their fathers without distinction. The custom appears to work peaceably and well, and is practised by all classes of the community. The effect of its existence is that there is a large surplus female population, who are provided for in nunneries, where they learn to read and copy the Thibetan Scriptures, and are otherwise engaged in religious services. It seems to prevail wherever the Thibetan language is spoken, even in districts on the Indian side of the mountain boundaries of the country, though, in places where the people have come much in contact with Hindus and Mohammedans, the reverse form—plurality of wives—is also to be found. The system is said to have existed since pre-historic times, so that the cause of its origin is speculative. It seems to be in no way connected with the Thibetan religion. The suggestion has been made that it arose in troubled times, when men were forced to be absent from home for long periods, and the defence of their wives and families devolved on the younger brothers left behind. The view which most travellers seem to adopt is that it owes its origin to the poverty of the country and the desire to limit the population. The custom may possibly be another form of that which existed in Biblical times, where it was the duty of the younger brother, in the event of his elder brother leaving no children, to marry the wife of his deceased brother.—*The British Medical Journal.*

The Bacterial Origin of Acute Otitis Media.—Dr. Netter says that acute otitis media is not always due to the same micro-organism. There are several varieties, each having a specific microbic origin, and each partakes of the characteristics of the germ which produces it. Streptococcus pyogenes is the most frequent pathogenic factor. They appear as chains of round or more or less long and flexible beads. Other bacteria may produce a fetid odor or a more fluid secretion. In eleven cases observed by the author, there was no preceding cachexia, with the exception of slight pharyngitis and coryza in two; one case followed tuberculosis; four cases complicated typhoid fever; two were consequent on measles. The otitis of streptococcus is often bilateral. In five cases the otitis was followed by complications evidently due to streptococci; these complications were superficial suppuration of the mastoid, suppuration of the mastoid cells, meningitis, phlebitis of the sinus, followed by purulent infection. Complications do not necessarily follow, but are always possible. The pneumococci of Fränkel may cause an otitis media; they were present in four cases. They may appear in typhoid fever and in other inflammations than pneumonia. The progress of this form of otitis is rapid, and the perforation is complete; meningitis may be observed, but recovery usually results. Staphylococcus aureus have been observed in the same cases with pneumococci. Netter found staphylococcus aureus in the discharge from four cases of otitis media. Fränkel and Simmonds discovered staphylococcus flavus in two cases, and Rohrer has seen staphylococcus pyogenes albus. The otitis media, in all its forms, is due to the presence in the middle ear of the parasitic organisms. They may penetrate through the Eustachian tube, and may enter the capillaries and be taken up by the blood; they may also enter the cranial cavity by the lymphatic system. All of the germs which have been observed in otitis media may be found in the healthy subject. To produce inflammation in the middle ear it is necessary that they should be present in sufficient quantity to become virulent. It is very rare that microbes are found in the blood or lymphatic vessels, their seat is usually the mouth or nasal cavity, and their numbers and activity may be lessened by antiseptic gargles.—*The Occidental Medical Times*, January, 1889.

To Blister the Skin Quickly.—Into a watch-glass, pill-box, or any similar small receptacle, pour ten drops of concentrated water of ammonia (aqua ammonia fortior); cover the liquid with a bit of linen or a little cotton-wool, and at once apply the cup upon the skin where the blister is required. Press so that the vapor is confined to the inside of the vessel. A red circle will directly be observed outside, when it will be certain vesication has taken place. Half a minute or so is all the time required to obtain the result. The blister may be dressed in the usual manner of dealing with a blister from cantharides. Acetic acid, concentrated, applied to the skin, will also in a few minutes produce vesication. In such cases evaporation should be prevented by some suitable covering. Bibulous paper slightly wetted with a little of the ethereal extract of cantharides, instantly applied to the skin and covered with a piece of adhesive plaster, will answer for the same purpose.

ACUTE PANCREATITIS.

A CONSIDERATION OF PANCREATIC HEMORRHAGE, HEMORRHAGIC, SUPPURATIVE, AND GANGRENOUS PANCREATITIS, AND OF DISSEMINATED FAT-NECROSIS.[1]

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

PART I.

UNTIL the time of Clässen [2] the evidence of an acute inflammation of the pancreas was almost wholly theoretical, and was not controlled by any considerable number of anatomical observations. Mercury was known to produce salivation, and the watery diarrhœa following its use was supposed to be due to irritation of the pancreas.

Influenced by this and other considerations, Schmackpfeffer,[3] having found certain alterations of the pancreas in a syphilitic woman who had been liberally treated with mercury, attributed her symptoms to the pancreatic changes. The latter he regarded as anatomical evidence of an acute inflammation. He describes [4] these changes as follows: "The pancreas was unusually dense, dry, and very much swollen; it was inflamed and red throughout, although more in the right than in the left side. Numerous drops of blood escaped from the cut surface. The duct was very much dilated, especially at its mouth. The gland weighed 5¾ ounces.

Some years later Neumann[5] stated that "death might take place within a few hours from a fatal metastasis of the buccal salivation to the pancreas. This happens when, in the midst of profuse salivation, the pulse sinks and quickens or the swelling of the salivary glands subsides and salivation is replaced by a green diarrhœa, while the skin is dry and shrunken." Under such circumstances the pancreas is found decidedly swollen, although but slightly reddened.

Clässen [6] knows of no observations in confirmation of Neumann's statement, and doubts its truth. He collects, however, a half-dozen cases, among them Schmackpfeffer's, of what he regards as fatal pancreatic inflammation, and from them he establishes the symptomatology of acute pancreatitis. The views thus obtained have essentially prevailed up to the time of Friedreich's article in Ziemssen's "Cyclopædia" in 1875.

The lesions found were as follows: In the second case, that of Juppin [7] "a section was made through the pancreas. Its tissue was dense and friable. It was a third larger round than normal; it encircled two-thirds of the duodenum, which it compressed, and it affected the pylorus also. . . . The pyloric opening was almost entirely closed, and the tip of the little finger could be introduced only with great difficulty and after repeated efforts. A vertical section through the pylorus showed it to be of almost cartilaginous density."

The third case is credited to Casper.[8] "All the organs of the remarkably handsome, though excessively fat, body were wholly normal with the exception of the pancreas. This was swollen to the size of a large fist, of cartilaginous density, firmly united to the duodenum, and in part to the stomach, and was of a brownish-red color. Its structure was not recognizable."

The fourth observation is also from Casper.[9]

"The pancreas was so much enlarged that its head was a half hand's-breadth wide, much infiltrated with blood, very dense, its structure not recognizable. In consequence of the enlargement of the gland its shape was more globular than round."

Rahn[10] is the authority for the fifth case. The stomach was dilated "almost to bursting," and was filled with clotted blood. "In the middle of the abdomen there projected from the abdominal aorta a dense, scirrhous tumor as large as the fist. It was intimately united to the aorta, and so compressed it that when the aorta was opened the finger would not pass through the narrowed canal. The narrowed portion was immediately below the origin of the cœliac artery. On close examination of the tumor with reference to its origin, the head of the pancreas was degenerated in this scirrhous mass, while the left part of the gland was in a wholly healthy state."

The sixth case is from Morgagni.[11] "The pancreas was unusually large, and contained round, tolerably large tumors of a density somewhat approaching that of cartilage."

To these is added another, possible, case from Lieutaud,[12] in which, after an acute attack of gastric pain, fever, vomiting, anxiety, and frequent fainting, "the pancreas was found much enlarged, hard, and scirrhous throughout. The left kidney was in a state of liquefaction."

The first case may have been one of mercurial poisoning; the second was one of probable malignant disease. The third and fourth are possibly of inflamed pancreas, but the evidence is insufficient to clearly establish the diagnosis. The fifth case may have been one of aneurism, while the last two are more suggestive of malignant disease than of acute pancreatic inflammation.

The common symptoms were deep-seated pain near the stomach, producing a peculiar anxiety, restlessness, perhaps frequent fainting. The pain bore no definite relation to the vomiting or other symptoms, and was not increased in proportion to external pressure. The vomiting was forcible, more or less greenish material being expelled. The abdomen was moderately tense, there was slight fever, and the appetite was but little disturbed and might be increased. There was a moist tongue, thirst, and constipation.

The effect of Clässen's treatment of the subject may be seen nearly thirty years later in the statement by Wardwell [13] that the prominent symptoms of acute pancreatitis are deep-seated, dull, epigastric pain, distention, sickness, and vomiting of a clear, greenish, viscid fluid; thirst, faintness, moist tongue, constipation, and slight pyrexia.

The first step toward an essential modification of these

views was made by Klebs, in 1870.[14] He preferred to say nothing about inflammation of the pancreas, but described the various lesions which have been found in and around this gland, without attempting to show their possible relations to each other. He availed himself of the cases published by Portal, Hooper, Löschner, Haller, and Klob, and of one in his own experience, to associate pancreatic hemorrhage with severe symptoms and to recognize the possibility of a hemorrhagic inflammation of the pancreas, already admitted by Rokitansky,[15] as a very rare occurrence. Klebs further recognized that this hemorrhagic inflammation might possibly result in a purulent peripancreatitis with partial sequestration of the gland.

Friedreich,[16] however, undertook to present a complete picture of acute pancreatitis more in accordance with the anatomical treatment of Klebs than with that of Clässen. He availed himself of the cases used by Klebs; in addition, of one reported by Oppolzer, and of another under his own observation. He suggested that acute pancreatitis was either primary or secondary. The former appeared to have a tendency to hemorrhage in the pancreas or in its vicinity, in which case a termination in gangrene and ichorous peripancreatitis might occur. If the acute pancreatitis became suppurative, multiple, minute abscesses were to be found, which tended to become confluent and to produce a resulting peritonitis.

The secondary variety of acute pancreatitis was either the granular degeneration found in infective diseases, or the circumscribed "metastatic" abscess. The possibility of a metastatic pancreatitis in the course of a parotitis was not to be absolutely denied, especially in virtue of the case reported by Schmackpfeffer.[17]

As there is a doubt of the existence of a pancreatitis in the case, it may be safely stated that there is no reason for admitting the existence of a metastatic pancreatitis secondary to inflammation of the parotid gland. It is evident[18] that an acute parotitis may arise during the course of a pancreatic inflammation. This single instance of association is presumably analogous to the occurrence of parotid inflammation in septic conditions of various origin.

Since Friedreich's anatomical recognition of an acute pancreatitis was based upon the consideration of four cases, he admitted his symptomatology of this affection to be neither precise nor complete. Furthermore, he seems[19] to include under the head of pancreatic hemorrhage those cases where this lesion is associated with necrosis and gangrene, and others where hemorrhage into the pancreas appears to be the sole cause of sudden death.

Klebs[20] had already recognized the existence of a suppurative peripancreatitis, and stated, presumably from his own observation, that in most instances this proceeded from lymph-glands. These were either the seat of metastatic abscesses or were primarily diseased by traumatic agencies or injurious food. Such abscesses were regarded as occasional causes of thrombosis of the mesenteric and portal veins. He recognized a possible eventual separation of the pancreas from surroundings by the extension of the suppurative process.

He thought it possible that the case of Haller and Klob,[21] already admitted as of hemorrhagic pancreatitis, might belong to this series, and regarded that reported by Gendrin[22] as illustrative.

In the light of the observations published up to the time of his article, Klebs regarded as of doubtful existence any pancreatic abscesses which did not arise from a peripancreatitis or from a suppurating cyst.

Important evidence as to the possible method of origin of a peripancreatitis was furnished by Chiari,[23] who found a round ulcer of the stomach communicating with the cavity of the omentum. The latter contained a spacious abscess with several openings into the jejunum. Lying free within this cavity was a shreddy mass of tissue, 12 ctm. long. It was brownish black, friable, and presented the structure of the pancreas.

Four years later, Chiari published the report of a case[24] by Schlossberger, in which the sloughing pancreas was discharged through the bowels. He reported still another[25] of earlier occurrence, in 1862. The sloughing pancreas, discharged from the bowels, was brought to Rokitansky by Trafoyer.

The next communication of especial importance in connection with the subject of pancreatic inflammation is that of Balser.[26] He calls attention[27] to the presence of nodules and patches of necrotic fat-tissue in the mesentery and in the contents of a cavity behind the mesentery. In the latter lay the pancreas also, attached to the duodenum, and its lobules appearing as if macerated. A second case was reported by him,[28] in which there were patches of necrosis of the abdominal fat associated with similar appearances in the pancreas. In addition, there was evidence of old and recent hemorrhage in the gland.

My own interest in this subject was first particularly aroused in 1876. At the request of Dr. J. P. Maynard, of Dedham, Mass., I made the post-mortem examination of a lady of uncertain age, not especially fat, who fell on the floor while apparently in her usual good health. She died within thirty minutes. In the meantime she complained of pain in the lower part of the chest. Her respiration became hurried, the pulse feeble; a short convulsion occurred, and death took place. The abnormal appearances found were several nodules and patches, the largest of the volume of a walnut, of freshly extravasated blood at the periphery of the posterior portion of both lower pulmonary lobes. There were several patches, of considerable size, of submucous hemorrhage near the ileocæcal valve along the mesentery. The pancreas was thin and very flaccid, with occasional slight, subperitoneal hemorrhages. Section through the organ showed similar hemorrhages in its substance. The gland-lobules were of a reddish-gray color, the general surface spotted with white specks. Microscopic examination showed extensive fatty degenerations of the gland-cells; many fat-drops, being exceedingly minute. The interstitial fat was frequently crystallized, and at times bundles of orange, acicular crystals (hæmatoidin?) were found.

The cœliac plexus was examined, and nothing abnormal found. The heart was contracted; its cavities contained mainly fluid blood. The mesenteric veins near the cæcum were injected. The liver and kidneys were injected; the spleen and suprarenal capsules were normal. Nothing abnormal was found in the brain or heart. It was considered, at the time, that the history of the case and the appearances found were best explained on the ground of Zenker's communication,[29] which will be soon referred to more particularly.

Since then it has been my opportunity, largely owing to the zeal of Drs. Gannett and Whitney, to have seen at least a dozen examples of pancreatic hemorrhage, with or without necrosis of fat-tissue, and of necrosis of fat-tissue without pancreatic hemorrhage. I have been present at several of the post-mortem examinations at which the diseased pancreas has been found, and have demonstrated to the students of the Harvard Medical School many of the specimens which have been removed by my friends and colleagues.

Having thus been impressed with the importance of the subject, I take this opportunity of utilizing the material which has been gradually accumulated by Dr. W. F. Whitney, the curator of the Warren Anatomical Museum. The value of this material is greatly enhanced by the records of the clinical course of the disease in question, which have been furnished by those in charge of the

patients. In addition, a collection of similar cases has been gathered from medical literature, which of late years has been especially prolific in this subject.

This paper will include a consideration of:

The liability of the pancreas to hemorrhage;

The association of hemorrhage with acute pancreatitis;

The occurrence of acute pancreatitis without hemorrhage; and

The relation of acute pancreatitis to fat-necrosis.

Pancreatic hemorrhage.— Although Klob [30] regarded interstitial pancreatic hemorrhage as not rare, he found it only, and then not constantly, in extreme portal stagnation.

Spiess,[31] however, in 1866, reported to the Frankfort Medical Society a case [32] of sudden death due to an extensive interlobular, pancreatic hemorrhage. His observation, though unique, escaped attention.

Klebs, as already stated (p. 198), had associated pancreatic hemorrhage with severe symptoms, and suggested that the hemorrhage might be due, in the absence of inflammatory changes in the interstitial tissue, to the corrosive action of the pancreatic secretion.

Zenker [33] then reported three cases as of fatal pancreatic hemorrhage. This lesion, however, existed in only two of them,[34] while in the third the hemorrhage was near the pancreas, in the hilus of the spleen. In this last case, and in one of the others, there was a striking venous injection of the solar plexus. He regarded this as the immediate cause of the sudden death, in accordance with the results of Goltz's experiment of cardiac paralysis by a blow on the frog's abdomen. He found in one of his cases a flabby heart with distended, empty cavities associated with marked injection of the abdominal organs, as in the frog experimented upon.

Prince [35] then published a paper on this subject, and Draper [36] reported a series of cases of sudden death from pancreatic hemorrhage.

Virchow,[37] however, in most recent times, has stated that nothing is more rare than hemorrhage in the pancreas.

The relative frequency and absolute importance of pancreatic hemorrhage is thus, unquestionably, a discovery of very recent origin. There are, however, a considerable number of recorded cases which show that sudden and unexpected death may occur, and a conspicuous hemorrhage be found in or near the pancreas as the sole significant lesion. Such hemorrhages may occur in a previously diseased pancreas or individual, or it may take place when the person is apparently in his usual health, and the pancreas gives no evidence of any acute disease.

Both groups illustrate the liability of the pancreas to hemorrhage, but the conditions of its occurrence must vary in each.

In the first series, the hemorrhage is associated with certain lesions of the pancreas of a chronic character. The earliest case of this sort, and one which has been quoted in evidence of pancreatic hemorrhage as a cause of sudden death, is that of Störck.[38]

A woman, aged twenty-eight, during the catamenial period, was seized with severe vomiting. The flow was arrested; chills, dyspnœa, and palpitation followed. Although she gradually improved, an epigastric pulsation became apparent, synchronous with the heart beat. After the next menstrual period this pulsation became more severe, and a resistant pulsating tumor could be felt below the stomach. The tumor increased in size, and there was a sense of weight in the epigastrium. During the subsequent three and a half months the symptoms improved, the palpitation became less, and the tumor smaller and softer. Sudden weakness then occurred, there was a rust-colored vomit, bilious stools, sudden increase in the size of the tumor, rapid emaciation, and death.

The pancreas was found so large and heavy as to weigh thirteen pounds. It formed a sac filled with blood, partly grumous and partly laminated. The stomach, intestines, and omentum were displaced and compressed.

The evidence here presented is not sufficient to exclude the possibility of the chief lesion in this case being an aneurism of some artery in the vicinity of the pancreas. If Störck's view be accpted that there was a hemorrhage within the pancreas, we have merely an illustration of what has been repeatedly found since his time, namely, hemorrhage into a pancreatic cyst.

The first indubitable case of this sort on record is to be found in the museum of the Harvard Medical School. It was published by Gross [39] from the MSS. furnished by Dr. J. B. S. Jackson, and has also been published by the latter.[40]

For several months before the patient's death a tumor was noticed in the epigastric and right hypochondriac regions. There were also signs of advanced phthisis. The patient sat up every day until a short time before his death. The day before this took place he was found partially comatose. The tumor was a cyst of the pancreas, containing from ten to fourteen ounces of bloody-looking serous fluid without coagula.

The conspicuously hemorrhagic contents of pancreatic cysts have been also noticed by Anger,[41] Küster,[42] Bull,[43] Kocher,[44] Wölfler,[45] Hagenbach,[46] and Steele.[47] The case reported by Pepper [48] as one of fatal hemorrhage from a pancreatic cyst admits of another explanation. The patient, an intemperate man, had frequently recurring intestinal hemorrhages for six months. He had two attacks of bloody vomit within five weeks, and finally an attack of gastro-intestinal hemorrhage, proving fatal in an hour. The blood came through an opening in the duodenum, a half-inch in diameter, near the common duct. A probe, passed through the opening, entered a cavity in the head of the pancreas of the size of a walnut. Its walls were trabeculated, but "everywhere covered by a smooth mucous membrane;" numerous crystals of hæmatine were lying on the surface. "But little of the proper gland-tissue was to be seen in this part of the organ, its place having been apparently usurped by dense fibrous tissue. The same state of affairs is also observable in the body and tail of the gland, although in a less marked degree." It seems more probable, from the symptoms in this case, the seat of the cavity, the nature of the duodenal opening, and the history of pancreatic cysts, that this was rather a case of perforating duodenal ulcer with corrosion of the pancreas than of pancreatic cyst opening into the duodenum.

Doubts are also to be entertained concerning Rugg's case,[49] reported as one of fatal hemorrhage from the pancreas. In 1843 he had a male patient, thirty-two years of age, who was rapidly recovering from a severe attack of acute rheumatism, but was up and dressed on the day before his death. He had frequently complained of severe pains in the epigastrium, but these had left him a few days before his death, and were replaced by acute pains in the left lumbar region. He was suddenly seized with agonizing pain in the latter place. His countenance became anxious, his lips pale, pulse imperceptible, skin cold and sweating, and death took place in an hour. The

pancreas was somewhat larger and harder than usual, and had a cavernous rupture in its anterior surface, having all the appearance of an excavated ulcer. Its cavity contained a bloody substance, about the size of a walnut, in concentric layers. On longitudinal section of the organ several of these sanguineous deposits were found, varying in size from that of a horse-bean to a hazel-nut, in appearance like aneurismal deposits. A large quantity of blood was extravasated over the left kidney. The probability of this case being rather one of aneurismal than of pancreatic hemorrhage is very strong.

Finally, the somewhat irregular case of pancreatic hemorrhage reported by Satterthwaite [60] may be mentioned. The patient, a man, thirty-six years of age, intemperate, syphilitic, had three attacks of jaundice in eight years. The last began five months before, and continued until his death. Toward the end of life he had a persistent bleeding from the lip, frequent intestinal hemorrhages, and constant drowsiness. The pancreas was distended beyond the usual size by a clot of blood. There was an extravasation of blood between the coats of the upper part of the ileum. The symptoms in this case are so different from those occurring in immediately fatal pancreatic hemorrhage, or in hemorrhagic pancreatitis, that the hemorrhage may best be attributed to the jaundice, like that from the lip and from the intestine. The pancreatic localization of hemorrhage in jaundice is exceptional, but need not be unexpected.

There remains, then, the following series of sixteen cases where pancreatic hemorrhage was apparently the sole cause of sudden and unexpected death, in persons not presenting evidence of other causes of death. Nine of them have occurred in or near Boston, and three of these are now for the first time published.

The following more detailed report of Case XV. is compiled from notes sent by Dr. Holt, of Cambridge, who made the post-mortem examination.

The patient, aged fifty-eight, was a gentleman of leisure, thin, white-haired, his body looking like that of a considerably older person. He was at a club-dinner the evening before his death.

He awoke about two o'clock the following morning, complaining of severe pain in the bowels, nausea, and great prostration. He was pale, and his pulse was very weak. He soon vomited, became collapsed, and died within half an hour.

The duodenal half of the pancreas was of a bluish red color, and was sharply contrasted with the yellowish-gray splenic end. The darker portion was infiltrated with blood, which lay in the interlobular tissue, and could be readily squeezed from the cut surface.

Nothing abnormal was found in the brain. Both sides of the heart contained a little fluid blood; the valves, cavities, and muscular substances appeared normal. The stomach was empty, and in the intestines were the products of digestion. The liver was normal in size and appearance, and the cortex of the kidneys was paler than the pyramids.

I am indebted to Dr. Williams, of Charlestown, Mass., for the notes of Case XVI., which occurred in his practice. It is included in the series, with the full recognition that it is open to criticism, since the post-mortem examination was necessarily partial and hurried.

The patient, a man, aged seventy, was a night watchman. His health had been good, and he had wholly abstained from liquor since early manhood.

In the evening he was suddenly seized with colicky pain in the epigastrium. After five hours the pain was almost constant, sharp, and cutting, extending toward the left, and downward nearly to the navel. The abdominal muscles, especially the recti, were very rigid. There was a slight, circumscribed, epigastric swelling at the left of the median line, extending from the costal margin to the navel. It was non-resistant and not sensitive to pressure, which rather relieved than increased the abdominal pain.

There had been vomiting of a yellowish fluid. The pulse was 95, regular, small, the radial and temporal arteries were rigid, the skin dry and not cool. The vomiting persisted, and in six hours the patient was collapsed, but conscious. He then became restless, the pain was less agonizing, and death took place sixteen hours after the beginning of the attack.

Dr. Williams' diagnosis was pancreatic hemorrhage.

After death he was allowed to make an incision over the tumor, and found the pancreas enlarged from the median line of the body to the splenic end of the gland. The enlarged portion was more easily cut than the rest and infiltrated with blood. On section, two or three ounces escaped into the peritoneal cavity. Slight mesenteric hemorrhages had occurred. There was no evidence of peritonitis, nor was any blood found in the peritoneal cavity before the pancreas was incised.

The following case, reported by Zenker,[61] is not inserted in the table, since it is not, strictly speaking, one of pancreatic hemorrhage, though important in suggesting the possible manner of death in this affection.

A man, aged twenty-eight, strong, very fat, and epileptic, was found dead, having been seen alive an hour before. There was a hemorrhagic infiltration in the hilus of the spleen and a venous hyperæmia of the solar plexus. The abdominal organs were strongly injected and the pancreas was fatty degenerated.

A consideration of the table on p. 203 shows that most of the individuals concerned were in their usual health at the time of the attack, or when last seen alive. They were invariably adults and usually beyond the age of forty, when the age was given. Some were conspicuously fat and strong, while a few were weak and thin. Although several were of intemperate habits, others were not so reported, and two were exemplary in this respect.

Two had complained of previous digestive disturbance, and one suffered from frequent abdominal pain. One had received a kick in the abdomen a week before death.

From the evidence here collected there is evidently nothing in sex, habits, condition, or exposure which will indicate the likelihood of pancreatic hemorrhage.

The cases and data are insufficient in number and detail to permit an exact clinical picture of this affection which shall be of especial value in a differential diagnosis.

We learn that pain was an early symptom in nearly one half of the cases; that it was usually severe, and might be intense, and was to be found in the abdomen or lower chest. Although mention is made of its presence in the epigastrium in one-fifth of the cases, this region is not conspicuously designated as the seat. On the contrary, there may be little or no pain, or merely a sense of constriction of the chest. Nausea or vomiting is but occasionally mentioned; constipation or a desire for frequent stools is still more rarely noted.

The most constant symptoms are those of collapse, and are more or less intense and more or less prolonged.

Death may take place within a half-hour after the onset of the symptoms and may be delayed for thirty-six hours. It is questionable in the latter instance whether the case should not, more properly, be included under the head of hemorrhagic pancreatitis than of pancreatic hemorrhage.

The appearances found after death are conspicuously the hemorrhage within and near the pancreas.

The gland may be of normal size, or enlarged, and its density may not be modified, or the pancreas may be flaccid, soft, and friable. The hemorrhagic infiltration is to be found in the subperitoneal tissue around the pancreas as well as in the interstitial tissue of the gland. The former may be continued into the omentum and mesentery, behind the colon and into the perinephritic fat-tissue.

[60] The Medical Record, 1875, x., 541.

[61] Loc. cit.

The entire pancreas may be infiltrated, or either half, or the central portion alone may be conspicuously involved. The hemorrhage is usually diffused, but it may be in numerous patches, both beneath the peritoneal investment and in the interlobular tissue. The color and moisture of the cut surface indicate that the extravasation is recent. It may take place into a normal pancreas or into one which is either fatty infiltrated, or fatty degenerated, or into one which shows a granular condition of the epithelium.

In a single instance evidence of an older hemorrhage was to be found in the presence of round, orange-colored bundles of acicular crystals. In the same pancreas were also to be seen colorless, acicular crystals, probably of fat, in clumps visible to the naked eye, corresponding to the appearances to be described under fat-necrosis. The microscopic examinations of one of Draper's cases showed occasional patches of hemorrhage within the lobules, although the infiltration was essentially in the interlobular tissue.

Hemorrhages might also be found in the wall of the duodenum and cæcum, and in the lungs in a single instance.

Although the splenic artery is reported to have been tortuous in one case, there is no evidence in any of a circumscribed aneurism. The splenic vein, when examined, was free from obstruction.

The conditions found by Zenker, viz., injections of the portal venous system and of the capillaries of the solar plexus, with distended and empty cardiac ventricles, were not generally met with.

Fatty degeneration and fatty infiltration of the pancreas were not necessarily present in these cases, and frequently occur without a trace of hemorrhage.

The seat, extent, and rapidity of the bleeding suggest that it is rather arterial than venous, and no evidence of venous obstruction has been found. Such hemorrhages are most likely to be of aneurismal origin, but aneurisms have not been discovered. An embolic source has been sought for in vain. It is possible that the pancreatic secretion may have corrosive properties, as suggested by Klebs, in which case the condition should occur oftener. Suggestive evidence in favor of this view is the fact, well known to demonstrators of anatomy, and called to my attention by my colleague, Dr. Mixter, that arterial injections are likely to break through and escape in the region of the pancreas.

Hemorrhages in a diseased or dead pancreas might be thus explained, but in the great majority of the cases collected there is no sufficient evidence of such disease. It is also possible that the hemorrhage may be of nervous origin, as in the pulmonary infarctions sometimes associated with cerebral lesions.

The only fact in favor of this view is the association of such pulmonary nodules with the pancreatic hemorrhages in one case. This observation, compared with the relative frequency of pulmonary hemorrhages of apparent central, nervous origin, makes the single instance of but little value as evidence.

That fat-necrosis is not a cause for such hemorrhage is obvious from its presence being suggested only in a single instance.

It is evident that the first step toward a more accurate knowledge of the immediate cause of this affection must lie in a more careful search for the actual source or sources of the leak.

Hemorrhagic Pancreatitis.—In considering the relation of hemorrhage to acute pancreatitis, it is im portant to agree upon what shall be understood by the latter term.

It has already been shown that the views advanced by Clässen and his predecessors give no aid in this matter. Klebs is non-committal on account of the paucity of evidence, and Friedreich elaborated his systematic description of acute, primary pancreatitis from the consideration of four cases. In the one pancreas were multiple abscesses; in another a bloody exudation, and infiltrated blood in the vicinity; in a third were spots of finely granular, yellow exudation with inter-lobular hemorrhage; while the fourth pancreas was gangrenous.

The material, which has been accumulating since the publication of Friedreich's article, in 1875, is already so considerable and varied as to make possible a more complete description of the subject.

The acute inflammation of a gland, from the anatomical point of view, demands the presence of degenerative changes in the parenchymatous cells, or an exudation in the interstitial tissue, or both these factors.

The first, the parenchymatous inflammation or granular degeneration of the pancreas, such as occurs in infective diseases, or as the result of mineral poisoning, is of no immediate concern. It is the interstitial variety, which, with or without associated parenchymatous changes, may be regarded as the genuine, acute pancreatitis; and it is in the interstitial tissue of the pancreas that the inflammatory exudation is to be sought. But this tissue is both fibrous and fatty, one or the other variety predominating in different individuals, and, perhaps, at different periods in life. These tissues bear a continuous relation to the peritoneum, and to the subperitoneal and retropancreatic fat-tissue. It is, therefore, most probable that an inflammatory process of this fat-tissue might arise within the pancreas, or be continued to the pancreas from some more remote place of origin. Thus a primary and a secondary, acute, interstitial pancreatitis might occur. The results in either case would be the same; the sources and progress of the disease might vary.

Whenever the anatomical evidence is insufficient to establish the diagnosis of inflammation, it is permissible to utilize the symptoms for this purpose. If the general symptoms of inflammation are present and the pancreas is described as infiltrated with blood, such an association of symptoms and lesion is rather classified among the inflammations than among the hemorrhages.

Thus Cases VIII. and XX. have many features in common; the latter, however, is tabulated as hemorrhagic pancreatitis, since it was considered clinically as a case of peritonitis from perforation. The former was placed among the hemorrhages, since the clinical picture was not that of an inflammatory process.

The series of cases which form the basis of this part of the subject naturally fall into three groups.

In the first hemorrhage is conspicuous, in the second suppuration, and in the third gangrene.

These may be designated respectively as hemorrhagic, suppurative, and gangrenous pancreatitis.

Before calling attention to the first of these groups it is desirable to exclude certain cases which have been regarded as possible illustrations of a hemorrhagic pancreatitis. Fearnside[52] reported the case of a man, aged forty-nine, not remarkably temperate, but who had enjoyed good health till within a year, since which time deep-seated pains in the region of the stomach had existed, with occasional heat or coldness in the same region, gastrorrhœa, pyrosis, constipation, pallor, and loss of flesh. For three months before death the pains became more severe and frequent, eventually constant, generally most distressing a few hours after food. Three days before death a sudden excruciating pain occurred, followed by jaundice and a dark-brown vomit. On the following day there was intermitting vomiting, and frequent hiccough. On the day of his death he was collapsed, although his intelligence was good. The epigastric pain was severe, and on pressure between the navel and the ensiform cartilage a deep-seated transverse tumor could be felt. The pancreas was four times the normal size, and was adherent to the stomach by some firm adhesions. The neighboring peritoneum showed spots of soft and firm exudation. The greatest increase in size was in the head, which extended deeply into the right lumbar region. It

[52] London Medical Gaz., 1850, xlvi., 967.

was blackish-brown, pultaceous, grumous, and contained distinct blood-clots. In the more consistent portions there was no trace of natural gland-tissue. The body was firm and close in texture, of a dark-red color mottled with black lines and points, and became paler toward the lip.

The probability of this being a case of malignant disease with hemorrhage is very strong, especially as the appearances do not correspond with those to be stated later as found in hemorrhagic pancreatitis.

Rigal [83] reports the case of a man, aged fifty-two, previously in perfect health, who suffered for seven days from intermittent fever, daily, with short remissions. The abdomen and legs then became swollen, and some pain was complained of at the right of the navel, where was a sensitive, indurated spot. Jaundice then occurred, also progressive weakness, and epistaxis. Finally fever was noticed, and death took place about seven weeks from the beginning of his sickness. The pancreas was large, the head being twice the normal size. The latter was brown, both on inspection and section. On microscopic examination there was advanced fatty degeneration, and numerous crystals of margarine were seen. There was also fatty degeneration of the right kidney, and an enlarged and friable spleen. The liver was normal in size and consistency, the bile-ducts and gall-bladder were dilated.

This case is excluded from the list which is to follow, from the inability to determine the nature of the changes in the head of the pancreas. At the same time it is admitted that certain characteristics are presented which render it not unlikely to have been an instance of the disease under consideration.

The case reported by Huber [84] must be excluded from those of hemorrhagic pancreatitis. His patient died within twenty-four hours after the onset of an attack of severe epigastric pain. There was a tumor of the head of the pancreas surrounding the common duct, which was passable. The tumor descended into the mesentery. It looked like Förster's carcinoma simplex, but had many pigmented and hemorrhagic spots.

The case of pancreatic hemorrhage reported by Challand and Rabow [85] is also not wholly clear with reference to its relation to pancreatitis.

The patient, sixty-two years of age, an insane woman, and inmate of an asylum, had an ovarian cystoma for several years.

She was found at bedtime pale, and groaning feebly, without known cause. The next day she was collapsed. She complained of suffering, especially in the lumbar and epigastric regions. The pain was not increased on pressure, and there was repeated vomiting. She remained in a condition of extreme weakness, with frequent vomiting and groaning, a quick pulse and a subnormal temperature, till her death, on the fourteenth day. The pancreas appeared doubled in size. On tearing its tissue a certain quantity of thick, black blood escaped. In making a longitudinal section, a cavity as large as the fist was opened, filled with large, black clots. The pancreatic tissue was dark brown, and so softened and friable that it was impossible to determine the point of origin of the hemorrhage. The duct was moderately dilated, and the tissues in the immediate vicinity of the gland were strongly discolored with blood.

This case is not included among those of hemorrhagic pancreatitis, since the described appearances do not correspond with those usually found, and the possibility of a pancreatic cyst or of an aneurism is not eliminated.

The list of sixteen cases shown in table on p. 203 includes the instances of associated pancreatic hemorrhage and inflammation which present common features of symptoms and anatomical changes. Of these cases three have occurred within the vicinity of Boston; two of these are now, for the first time, reported, and the gross and microscopic specimens from the latter are submitted to your inspection.

I am indebted to Drs. Pinkham and Whitney for their notes of Case XXVIII. The patient was a man, forty years of age, by occupation a caterer. He was liable to attacks of acute indigestion, and, for a year or more before his death, had suffered from general malaise and debility. His discomfort was attributed to indigestion. His last illness was of six days' duration, and was characterized by epigastric pain, vomiting, and by great cardiac weakness. Death occurred from heart-failure after the pain and vomiting had ceased.

There was a large quantity of abdominal fat, and the post-mortem examination was negative, with the exception of the appearances described below. The pancreas was very large, weighing, with some adherent fat, four hundred and ten grammes. The cut surface showed everywhere dark-red streaks and patches between the lobules, and separating them to a slight degree. On microscopic examination there was no evident alteration of the gland-cells. A considerable quantity of free blood-corpuscles was found in the intra-lobular tissue. The fat-tissue was everywhere filled with small, opaque-white spots, often with a well defined, dark border. Their diameter varied from a few millimetres to several centimetres. They were present within the pancreatic fat-tissue and in that outside the organ. Microscopic examination showed that the fat-tissue was changed to a finely granular mass in which were numerous very fine acicular crystals. In the vicinity of the patches of necrotic fat-tissue were found colonies of micrococci.

For the purposes of this paper a more extended microscopical examination has been made of the above pancreas.[86]

There is an extensive inter- and intra-lobular infiltration of fat-tissue. The inter-lobular fibrous tissue is increased in places, and the contained duct is widely dilated. The pancreatic lobules are, at times, diffusely stained of a brownish-yellow color. Certain lobules contain clusters of orange-colored, acicular crystals, especially in the vicinity of the fat-tissue. The inter-lobular fat-tissue shows circumscribed, as well as diffused, hemorrhagic infiltration. There is, in addition, an excessive accumulation of round cells, in places wholly cellular, again fibrino-cellular, entirely replacing the fat-tissue. There are sharply defined islets of fat-tissue in which the individual cells are indistinct, without nuclear staining, the whole filled with acicular fat-crystals. The border is often sharply defined by a zone, in which are small, round clumps of orange-colored, acicular crystals, and outside of which a line of round-celled accumulation is frequent. Bacterial clumps and venous thrombi are present.

The described changes in the inter-lobular fat-tissue are likewise seen in the parapancreatic fat. The following is the history of Case XXXIII., for the notes of which I am indebted to Drs. J. J. Putnam and Whitney. The patient was a gentleman, forty-eight years of age, who had been hemiplegic for several years. He was well-nourished but not excessively fat. He had suffered from several attacks of pain in the region of the stomach, with chilly sensations, from which he recovered in the course of twenty-four hours. They were usually attributed to indigestion, but no exciting cause was ever discovered. He had one severe attack of this sort a year before his death, and became collapsed, and was covered with cold sweat. His mind was dulled and his talk somewhat incoherent. He rallied under the use of stimulants, and in the course of a day or two appeared in his usual health.

At 5 A.M. he was seized with a severe stomachache, and a few hours later vomited, with temporary relief to the pain. Throughout there was considerable dull epigastric pain, and occasional nausea and vomiting. In the

Speedy vomiting, collapse. Death within one-half hour.	Duodenal half of the pancreas infiltrated with blood. Each side of the heart contained a little fluid blood.
XVI....	Williams: MS. Notes, v., p. 55. 1888.	M.	70	Thin; temperate. Always well.	Sudden epigastric pain, vomiting, weak pulse, slight epigastric swelling, collapse in a few hours, and death in sixteen hours.	Tail of pancreas infiltrated with blood. Slight mesenteric hemorrhage. No evidence of peritonitis.

evening, immediately after vomiting, he suddenly became collapsed. There was constant pain throughout the night, and restlessness. During the second day he improved somewhat, although annoyed by hiccough. He vomited chiefly mucus, in which were found several small dark-red lumps about the size of peas.

Early in the third day he was very restless, cold, and livid, his breathing rapid, and his pulse almost imperceptible. He was conscious but anxious, and died within six hours after the collapse became extreme.

The pancreas was about twice the normal size; on section, of a dark-red color mottled with opaque-white spots and patches, which lay between the lobules of the gland. These changes were most marked in the body of the gland, the head being relatively normal. The fat-tissue near the pancreas, that in the root of the mesentery, and in the meso-colon near the spleen, was of a dark-red color. In places it was soft, discolored, and foul-smelling. Numerous opaque, grayish-white spots were visible beneath the mesenteric peritoneum. The splenic vein contained a soft, dark, adherent thrombus which was continued into some of the pancreatic veins. Recent thrombi were also found in some of the mesenteric veins. The spleen was slightly enlarged, the pulp increased and dark red.

There was no infiltration in the vicinity of the solar plexus and semilunar ganglion.

There was no evidence of a peritonitis.

In the microscopic examination of the hardened pancreas there is seen a sharp differentiation of the section into three zones.

The intermediary zone represents the inter-lobular fat-tissue which is continuous with that around the pancreas. It is not only extensively infiltrated with blood, but is often transformed into a porous structure from the apparent destruction of fat-cells. Elsewhere it contains a fibrillated meshwork, finely granular material, bacteria, and numbers of acicular fat-crystals. There is also an occasional round-celled infiltration of this fat-tissue between the relatively normal portions of the pancreas and the hemorrhagic and necrotic inter-lobular fat-tissue.

On the one side of this intermediary zone the acini are distinctly defined and the nuclei clearly stained. Occasional lobules are seen with granular epithelium and indistinct nuclei. There are, in places, an intra- and inter- lobular infiltration of blood-corpuscles and numerous accumulations of round cells. The inter-lobular tissue shows a fibrillated meshwork, apparently clotted fibrine; in the smaller ducts are numerous leucocytes.

On the other side of the hemorrhagic zone, although the lobules are distinct, the borders of the acini are often confused. The cells are granular, frequently not differentiated, and there is no staining of the nuclei. At times

the lobules are replaced by a granular detritus, or the cells are widely separated from each other. Here and there among these necrotic acini are stained islets, apparently bacterial colonies, thrombotic veins, and, more rarely, small accumulations of round cells. At the edge of the pancreas is a large venous thrombus containing innumerable bacteria.

Of the seventeen cases of hemorrhagic pancreatitis fourteen were males and two were females, the sex of one person not being stated. Their ages were as follows: —

Years of age.	Number of cases.
From 25-30	1
" 30-35	2
" 35-40	1
" 40-45	4
" 45-50	1
" 50-55	1
" 55-60	2

One was described as a young adult, two as adults, and nothing was stated concerning the age of two.

The patients were usually in good health at the time of the attack, a few of them being conspicuously strong and robust. Nearly one-half of them were abundantly or superabundantly provided with fat-tissue.

A small fraction, nearly one-sixth, was addicted to the abuse of alcohol. Nearly one-half of the cases suffered from previous attacks of indigestion. These attacks were usually characterized by pain which was colicky, gastric, or abdominal, and so severe in one instance as to suggest impending perforation. Vomiting, either watery or bilious, or both, was noted. Nausea, belching, and diarrhœa were recorded. Jaundice occurred in a single instance.

It is obvious from the above statement that the previous digestive disturbances were rather gastric, or gastro-duodenal, than enteric. The immediate attack began, in the great majority of cases, with abdominal pain, usually without known cause, though rarely some irregularity in diet appears to have been an immediate predecessor. The pain was violent, intense, or severe, either constant or paroxysmal. Its seat was usually in the upper abdomen, and, in one instance, was stated to have followed the course of the pancreas; subsequently, in one-fifth of the cases, the abdominal pain became general. The initial pain was usually followed by vomiting, more rarely by nausea alone. In one case there was a conspicuous record of no vomiting. The vomiting was constant, repeated, or occasional. It might be copious. It was bilious at times, or black, and contained, in one instance, dark-red clumps the size of peas.

Constipation was a symptom of frequent occurrence, and a diagnosis of intestinal obstruction was made in three instances, in one of which laparotomy was performed. The occurrence of diarrhœa was noted in but one case. Hiccough and albuminuria each were reported in a single case.

Fever was an inconstant symptom. When present it was of early occurrence, and might be high on the second day. On the contrary, the temperature might be normal on the first day and subnormal on the following day. Delirium was present in three cases.

A tympanitic swelling of the abdomen was of no infrequent occurrence. It was usually general, or in the upper abdomen, and was generally localized in the lower abdomen. In one case, thought to be of intestinal obstruction, a swollen intestinal convolution was to be felt in the right side.

Symptoms of collapse were almost invariably present, and usually directly preceded death.

This occurred as follows:

On the 2d day in	3 cases.
" 3d "	5 "
" 4th "	3 "
" 5th "	2 "
" 6th "	1 "

It took place after a few or several days, each in one case. The diagnosis lay between intestinal obstruction, perforative peritonitis, and an irritant poison. The pancreas was found enlarged, either throughout or at one extremity, usually at the head. The gland was frequently doubled in size, and might seem still larger when abundant fat-tissue was present. The enlargement has been compared to the size of a man's arm. The gland was generally dense, sometimes friable, and has been noticed to be of diminished consistency. The existence of hemorrhage was usually suspected by the appearance of the surface, which is of various shades of red. On section, however, the color may be dark-red, reddish-brown, violet, reddish-black, or even black. The modification in color may be uniformly distributed, or lie in patches, or in specks. The patches correspond with nodules which may project above the surface. These discolored patches may show white specks or streaks, and the red color may lie in the inter-lobular tissue of the pancreas.

The color of the section may be affected by the presence of associated alterations, one of which is accidental, the other may be incidental. The former is due to an excessive quantity of fat-tissue in the pancreas, sometimes appearing to form nodules as large as hazel-nuts, and to treble the size of the gland. Bands and spots of a translucent yellow are thus produced which are mottled with shades of red. The incidental appearance is due to the presence of opaque-white specks, spots, and streaks, which are generally known, since the publication of Balser's[87] article, by the term fat-necrosis. These were seen in six of the cases, and it is not improbable that the granular exudation described by Löschner may have been of the same nature.

The pancreatic duct may contain a bloody, ichorous fluid, and its branches may be plugged with clotted blood. The duodenum and jejunum may show swelling, injection, and ecchymosis. The hemorrhagic infiltration may be found beyond the pancreas, both in the parapancreatic tissue, mesentery, meso-colon, and in the omentum. It may extend downward behind the descending colon, nearly to Poupart's ligament, and may be found at the outer border of the left kidney. The splenic artery and vein are usually free from changes. The latter may contain a thrombus. The portal vein has been found free from thrombosis. The condition of the other organs is essentially negative. The heart may contain liquid blood, or a differentiated clot may be found in the right ventricle. The spleen may be small, with wrinkled capsule, or it may be slightly enlarged and injected.

The Agency of Drinking-water in the Causation of Cholera.—In a report of Chief Engineer F. G. McKean, U.S.N., on the Takashima coal mines of Japan, reference is made to the means taken to prevent cholera by the use of distilled water. He reports that until the last year cholera appeared regularly on the island (Takashima), and made great ravages in its dense and peculiar population. It is stated that during ten days of 1885, nine hundred persons died of the disease, so that it became necessary to construct special furnaces for burning the dead. It was suspected that the germs were in the water brought from the mainland for drinking purposes, and hence the distillers were put in operation, and stringent orders issued that the water from the mainland was only to be used for washing purposes. Last year there were no cases of cholera on Takashima, though it raged on the neighboring islands, and the immunity is affirmed to be due to the purity of the drinking-water.

An Indian Coroner's Verdict.—The following coroner's verdict is in print, apparently a specimen of Baboo English, that is, English as written by a native of India. This was rendered upon an ill-fated Hindoo. "Pandoo died of the tiger eating him; there was no other cause of death. Nothing was left except some fingers, which probably belonged to the right or left hand."—*Boston Medical and Surgical Journal.*

SOME OF THE ABUSES OF ETHERIZATION.[1]

By GEORGE F. SHRADY, M.D.,

NEW YORK.

MANY points connected with anæsthesia have come up from time to time before this Society, and there has appeared such a disposition on the part of some members to discuss them that it has occurred to me that an opportunity for so doing might be afforded by a few general remarks on the abuses of etherization.

Notwithstanding etherization is so extensively practised, much is yet to be learned concerning many of the simple details of its administration. Especially is this the case with matters which bear upon the comfort and safety of the patient, and upon his subsequent state of health. In what is to be said, it must not be understood that there is special need for emphasizing precautions or formulating rules for members of this Society, whose large experience in hospital work is a guarantee against accident or carelessness, but as a result of the saying, some good may come to those who may wish to know what is believed to be the safe and accepted method of the present day. In other words, it may be interesting to know what experience has taught us to do, and what to leave undone in many of the various conditions which govern anæsthesia. Let us premise by asserting that we shall confine our remarks exclusively to the abuse of ether, leaving for the present, at least, chloroform entirely out of the question.

Ether is generally believed to be a safe anæsthetic. While this is in the main true, it is equally true that on this account we are often given to use it quite recklessly. The English characterize the American method of administering ether as rude, dangerous, and oftentimes actually cruel. They speak of it as the drenching plan. This criticism is founded on a great deal of truth.

In one of the larger hospitals of this city, for a long time, there was hung in the consulting-room a graphic picture of the struggle in "getting a patient under ether," at least that was the title. To the unsophisticated eye it suggested a lively rough and tumble scramble to get the poor patient under the numerous attendants. There was such a confusion of flexed elbows, crooked knees, bent backs, bowed heads, climbing postures, and flying coat-tails, that it was difficult, except for his presenting foot, high in air, to make out which end of the poor victim was at the head of the table. Every one who had never been anæsthetized in this way smiled when he looked at it. To any patient who had been through it all, there was the keen appreciation of the desperate goneness of the under-dog in a fight. Every one has seen the original battle in progress, but as the poor laid-out dog generally comes out alive the smothering scene becomes merely an amusing part of the play.

So many patients have complained of the immediate and after-effects of such treatment that it appears almost a conscientious duty on my part to speak for them. It is impossible, within a given compass of time and space, to do more than refer to the sufferings, suspense, shock, and even agony of fear which they have endured during these ordeals. But there is scarcely a surgeon who has not heard similar experiences. In nothing is the grim doctrine of being cruel to be kind, more strikingly exemplified as in instances of what is now termed rapid anæsthesia.

In some general remarks upon the abuses of anæsthesia, what grow out of them, and their remedy, I am convinced that we cannot go far out of the way in introducing the rapid or drenching method as the head and front of the offending. What I mean by the rapid method is this: When everything is ready for etherization to begin, the sponge is saturated with ether, and the cone or inhaler crowded upon the patient's mouth and nose, and forcibly held there until the struggling ceases and the patient becomes quiet. It is a simple smothering process from beginning to end. It is not difficult to assume that this is all wrong, and that the only possible excuse for it is that it saves time. Against the latter is oftentimes weighed many of the distressing sequelæ of shock, which we see even years after the anæsthesia has been experienced.

In the category of shocks of anæsthesia the crowding method takes a first place. Nothing can be more demoralizing than to choke a patient suddenly and forcibly with an irritating vapor, without the chance of an appeal for a single breath of fresh air. All the sensations of actual impending asphyxia are present of necessity. Natural breathing is almost as effectually shut off as if the head were held under water.

It is not contended that the pure vapor of ether cannot be breathed with safety; but the time for proving it is not with suddenness and when the lungs are mostly filled with residual air. It is on account of the latter condition of things that nature rebels in desperate struggles against the sense of suffocation. The residual air is five or six times more than the respiratory tide, and is thus completely shut in, and partially charged as it is with gases that should have a ready escape. It is this anomalous state of affairs which doubtless gives rise to those reflex struggles for breath which are remembered by patients with so much horror long after the other experiences connected with the operation are forgotten.

How much more rational it is to allow the lungs to empty themselves of the residual air by a gradual process of forced expiration. The latter means keeping the sponge from direct contact with the face until the ether vapor takes the place not only of the respiratory tide but of the residual air. This method not only encourages the patient to breathe easily, calms his fears, and reduces the shock, but has a tendency to mitigate, if not to absolutely control, those reflex muscular excitabilities, which in the shape of tetanic spasms of the respiratory muscles—cough and vomiting—are so apt to interrupt and endanger an otherwise peaceful sleep.

As soon as the ether vapor occupies the lungs, and when primary anæsthesia occurs, the cone or other apparatus can be brought in contact with the face. The patient then breathes without difficulty the denser ether vapor. This is what may be called the gradual and rational method, the only so-called lost time being the period before primary anæsthesia is established.

It might appear to be absurd under the circumstances to dwell on the advantages of the latter procedure were it not for the fact that the rapid-drenching, struggling, method is the one most in vogue with the junior assistants in our hospitals.

And this leads me to refer in passing to these gentlemen in connection with some of the abuses we have to consider. They are generally juniors, almost always inexperienced, and therefore quite self-confident. It is not so much their fault as it is that of the men who should teach them their duties. It is notoriously true that no responsibility of equal importance is more lightly considered and less preparation made for it than that connected with the administration of an anæsthetic. By the time a young man learns passingly well to give ether, his place is taken by a fresh hand, and so on, term after term, and year after year, until the operator, constantly annoyed by interruptions and threatened accidents, accepts the situation as one which apparently admits of no easy remedy.

Very many of the abuses of ether are chargeable to faulty administration of the drug. They begin wrongly and generally end wrongly. I say it in all meekness of spirit, for many a time have I been quietly rebuked by the amused surprise of members of my hospital staff when I have offered a criticism on what, from a traditional standpoint, they consider a very unimportant matter.

[1] Read at a meeting of the Practitioners' Society of New York, January 4, 1889.

As if to atone for carelessness and inattention during the administration of the drug, they are more than ready to abuse the patient by fussiness and over-concern regarding trivial occurrences. Then comes in the sin of commission to atone for that of previous omission. Let the patient miss a respiration or two, the jaw is pushed forward, or the tongue pulled out, or the chest punched for artificial respiration. All of which is as unnecessary as the constant caressing of the eyeball, or the forcible, almost brutal, control of the muscular jerkings of the patient. In the vast majority of cases, if the patient is carefully and evenly kept under ether, the less he is meddled with the better, and the less force that is used upon him the less trouble he will give and the better he will be afterward.

Aside from keeping the patient the shortest possible time under ether, there is nothing of more importance than the steady and even method of its administration. The administrator should watch his patient as carefully as does the engineer his engine, and should appreciate the slightest indication of a faulty stroke or irregular pressure. The difference between this and the interrupted method is that between the results of a refreshing sleep as contrasted with the grim experiences in fighting a nightmare. As a consequence, the shocks are diminished all along the line. A steady strain is always born better than a succession of jerks. Everything should be done to keep the patient quiet. Even the reflex muscular movements should be passively rather than actively controlled. Nothing tends to excite a patient more, when partially under ether, than to use direct force in restraining him, or in speaking harshly to him. In fact, it is a good rule for the operator and assistants never to indulge in any conversation during the partially insensible period of the patient, as the hearing is the last sense to succumb to the narcosis.

When full anæsthesia is established and the condition is carefully maintained the patient is apt to remain quiet during the entire operation giving the assistants but little trouble. It is oftentimes the unnecessary interruptions which grow out of officiousness of attendants which prove the exceptions to the rule. There are many phenomena that mean nothing, which are incidents rather than accidents, but which are constantly magnified into undue importance. For instance, nothing is more common than a complete stoppage of respiration for an instant just before complete anæsthesia occurs. This is so apt to alarm the novice that he is inclined to punch the patient's chest, forcibly pry open the clenched teeth, slap his face, and hurriedly go through with efforts at artificial respiration. If he waits a few seconds and gives the patient a chance there will be a full inspiration, and the respiration will go on as easily and naturally as before.

Most of the abuses attending anæsthesia are occasioned by carelessness on the part of the administrator in either giving too much or too little of ether. But in spite of good judgment and care, more or less trouble sometimes ensues. Many patients bear ether badly, and in operations of emergency we cannot select our cases. Bronchorrhœa is oftentimes very distressing, even with patients who have no lung trouble. But even this condition is modified and mitigated by an easy and uninterrupted administration.

A few words may be said here in regard to the prevention of the real accidents in connection with mechanical arrests of respiration.

Vomiting is always a bugbear. There are apparently no rules for its prevention. Patients with full stomachs and with empty stomachs alike suffer from it. The rule is always to have the stomach empty before etherizing. The possibility of food lodging in the trachea is always to be borne in mind, but this accident very rarely occurs. I have often been compelled to operate upon a patient after he has had a full meal, but never experienced more than a temporary trouble from vomiting. Simply lowering the head and turning it to one side are all that is required. After this the disposition to further vomiting is often prevented by deepening the anæsthesia.

Whenever anything unnecessary is done for a patient who is helpless it amounts to an abuse of the situation. When we consider it from such a stand-point there are more abuses than we can count on our fingers within the decimal range.

Patients complain of sore cheeks and necks for days after the operation, because the administrator, for perhaps an hour at a time, had been bracing his thumbs against the angles of the jaws in the fear that the epiglottis might elude his vigilance and shut up shop, or that the unruly tongue might dodge too far backward into the pharynx. This constant bracing of the jaws is one of the recognized accomplishments of the anæsthetizer. It has the portentously calm assurance of readiness in prospectively dreadful emergencies. The patient, in fact, appears to be safe against any accident so long as the thumbs of the man at the helm hold out. In truth, whatever can be done in pushing forward the lower jaw can be done quickly, effectively, and without force. The same may be said in regard to pulling out of the tongue. When that organ is curled backward so as to impede respiration it can be gently drawn forward for an instant, and that is all sufficient. Traction on the tongue has less good effect than is generally supposed. The action is limited by the frænum in front and the anterior faucial pillars behind, and is only useful when the dorsum of the organ is curled upon itself and when there is a general relaxation of the sublingual muscles by a flexing forward of the chin. Generally under the latter conditions the simple elevation of the chin and extension of the neck will promptly relieve the patient and save his tongue from the stretching and scraping of clawed forceps. In connection with this point it may be interesting to refer to some recent experiments of Dr. Benjamin Howard, of London, by which he attempts to establish a simple and available method of elevating the epiglottis by forcibly extending the neck and head backward. He claims that by this means the hyoid bone, the attached hyo-epiglottic ligament, and the genio- and myo-hyoidean muscles become fixed points, when the epiglottis irresistibly moves upward and the entire pharynx becomes enlarged throughout. I have not had occasion to try this method, but refer to it in passing as possibly affording assistance when other means may fail.

In considering the immediate and after effects of ether, the fact cannot be too strongly impressed that, all other things being equal, the less we give of the drug, and the shorter the period of profound anæsthesia the better. A patient should not be any longer under its full influence than is actually required for the performance of the really painful part of an operation. The lack of this precaution in subjecting the patient to an extra shock has sometimes led to fatal results which have been unjustly laid to ether. On the other hand, there should be no excuse, short of actual danger to life, for allowing the patient to suffer any pain during the operation.

There is often considerable difficulty in anæsthetizing patients who have been addicted to alcoholic stimulants. They are more apt to be violent and rebellious under restraint, and a longer time is usually required for anæsthesia to declare itself. In such cases it is well to administer an hypodermic injection of morphine ten or fifteen minutes previous to etherization. Under these circumstances the patient comes not only more quickly under the anæsthetic, but the effects of the latter are prolonged by the morphine. In fact, a proportionally less quantity of ether is required, especially during the less painful parts of an operation, and not unfrequently the ether can be dispensed with altogether, the morphia taking its place. This is of especial value in lengthy operations, in which it is necessary to reduce the shock of anæsthesia as much as possible. This mixed narcosis is also of great use in those cases which, by frequent operations, have developed a tolerance for ether. This latter condition was strikingly illustrated in a case in which twenty-two etherizations were necessary for

a series of plastic operations performed at different times during a period of three years. In that instance, without morphine, nearly a full hour was required, while but half that time was consumed when morphia was used.

It is not the purpose of these remarks to refer in detail to many of the disagreeable sequelæ of anæsthesia, which last for varying periods after its administration. Among these may be simply mentioned protracted nausea, more or less persistent bronchorrhœa, headache, giddiness, suppression of urine, and choreic symptoms. Aside from proving that ether is a powerful drug, their occasional occurrence emphasizes the great importance of care and limit of time in its use. It is well conceded that etherization is sometimes dangerous when albuminuria exists, or when there is embarrassed respiration the result of empyema, and in some forms of heart trouble, and that very often, choreic symptoms occasioned by etherization last for months afterward. I am convinced that most of these sequelæ are due to careless or too heroic etherization.

While it is fair to assume that ether is a safe anæsthetic, the exception to the rule obtains much oftener than is reported. Every surgeon finds himself from time to time in a very tight place, in spite of the greatest care on the part of the administrator. It is only the conventional idea that a patient has no business to die under ether that allows the fact of an accident to go by default. It is mentioned casually, perhaps, but that is all. We have all been there and gone on. Under such circumstances each operator has his own methods. Personally, aside from straightening the tongue and opening the glottis by closing the mouth and gently pressing the lower jaw forward, I believe in the efficacy of inversion of the body and judicious attempts at artificial respiration. I have occasionally used nitrite of amyl, by inhalation, with striking benefit, but have never seen a case in which I was willing to try the galvanic battery. I have an impression, shared by many others, that the battery, as a rule, does more harm than good.

In order to avoid many of the abuses of anæsthesia, to which we have referred, we may offer the following conclusions, upon which a fuller discussion may profitably turn:

1. In commencing the administration of ether the gradual method is to be preferred.

2. Its employment allows the lungs to empty themselves of residual air, prevents coughing and struggling, and places the organs in the best possible condition to receive and rapidly utilize the ether vapor.

3. After the stage of primary anæsthesia is reached, the more pure ether vapor the patient breathes the better.

4. The shorter the time of anæsthesia, and the smaller the amount of ether used, the less likely are the unpleasant sequelæ to occur.

5. The more evenly it is administered the less shock to the patient.

6. Anæsthesia should be entrusted to experienced administrators only.

7. Many of the fashionable efforts to resuscitate patients are not only useless but harmful.

8. The minimum amount of force should be employed to restrain the muscular movements of the patient.

9. Mixed narcosis is often advisable for prolonged operations.

10. The utility of the galvanic battery, in threatened death, is yet to be proven.

11. The most trustworthy means of resuscitating desperate cases are artificial respiration, hypodermic stimulation, inhalation of nitrite of amyl, and inversion of the body.

247 Lexington Avenue.

The Therapy of Tuberculosis.—The fund for promoting the study of the treatment of tuberculosis, which is being raised in France, amounts now nearly to fifteen thousand dollars.

A REPORT OF FORTY-TWO CASES OF INTUBATION AT THE WILLARD PARKER HOSPITAL, NEW YORK CITY.

By F. K. PRIEST, M.D.,

RESIDENT PHYSICIAN.

In a series of two hundred and sixty-six cases admitted to the Willard Parker Hospital, intubation was performed for the relief of laryngeal stenosis, in forty-two, or a little over twenty-two per cent. of that number, with a percentage of recoveries of 26.19.

The majority of these cases were of undoubted diphtheria, with well-marked symptoms of laryngeal stenosis, at the time of admission, while many of them had been without proper care or medical treatment and were well-advanced in the last stages of septicæmia, the operation being performed merely for the relief of the stenosis, with no hope of ultimate recovery.

Of the forty-two cases eight were cases of diphtheria complicating or accompanying other contagious diseases, as follows: one case of measles and diphtheritic conjunctivitis; one of varicella; and six of scarlet fever.

In thirty-five of the forty-two cases membrane was present in the throat or anterior nares, or coughed out either before or after the introduction of the tube; in the seven remaining cases, the presence of membrane was not detected at any time during the course of the disease, although there was more or less swelling of the cervical glands with discharge from the nostrils. Only one of the seven recovered.

On admission in twenty-nine cases, the symptoms of laryngeal stenosis were well advanced, twenty-five of this number being unquestionably diphtheria, and one case in which the presence of membrane could not be detected, a large piece was coughed out during the introduction of the tube. In five cases there was a hoarse, croupy cough without dyspnœa, and in eight the laryngeal symptoms developed after admission.

In all cases where the character of the dyspnœa and the general condition of the patient permitted of the delay, intubation was not resorted to until other means for the relief of the stenosis had been tried and failed to give more than temporary relief.

In three cases only, where the urine could be obtained, albumin was not found on examination, several dying from acute nephritis with suppression of urine, as occurred once five days after the removal of the tube, all local evidences of diphtheria having disappeared at the time. This one has been included in the list of fatal cases, as the patient was not discharged from the hospital, although it might be considered as a successful case of intubation.

In those cases that recovered, the average time the tube remained in the larynx was six and one-half days. No definite rule, however, was followed as to the time of removal.

In cases that were progressing favorably the tube was left in position until the membrane had disappeared from the throat and nose and the fever had subsided.

The tube was removed in one case on the fifth day, the membrane being still present on the tonsils; on account of violent and persistent coughing and vomiting after taking fluids, the urine was also scanty, high colored, nearly three-fourths albumin; after which the cough was less troublesome, vomiting ceased, and the child took plenty of fluids; although the breathing was somewhat stridulous there was no return of the dyspnœa.

Coughing after drinking was a constant symptom and, in several cases, it was severe enough to induce vomiting. The above case was the only one, however, in which this symptom was severe or constant enough to seriously interfere with the ordinary feeding or treatment.

The most troublesome complication, and one that in several cases was productive of very alarming symptoms, was from the collection of mucus in the throat and con-

sequent obstruction of the tube. This was found especially apt to occur in very young children during the night or early hours of the morning, the child being unable to expel, by coughing, the mucus that gathered in the throat during sleep; as a result the respirations became labored and, if not relieved, gave rise to intense dyspnœa, interfering with the circulation, and, in fact, all the symptoms of stenosis of the larynx. For the relief of this symptom syrup of ipecac, in doses sufficient to produce vomiting, was given with good results, the act of vomiting expelling the mucus, and relieving the dyspnœa without disturbing the tube. Emesis was thus induced several times in one case, which afterward recovered.

The removal of the tube was always followed by more or less stridulous breathing, lasting from a few minutes to several hours, and in several cases by dyspnœa coming on in a few seconds or minutes and rapidly becoming alarmingly stenotic, necessitating the immediate reintroduction of the tube. In a child one year of age, the tube was coughed out on the fifth day, symptoms of stenosis suddenly appeared and the patient became unconscious; tracheotomy was immediately performed. The child revived and was apparently as well as before the tube was removed, but died quietly eight and one half hours after the operation.

In three cases, the removal of the tube was followed by symptoms that seemed to point to ulceration of the larynx or trachea, and in one in which a partial autopsy was obtained such was found to be the case. This was a child one year of age, with a marked croupy cough on admission, membrane on the tonsils and pharynx, which developed laryngeal stenosis on the third day when the tube was introduced, the membrane having disappeared from the throat on the sixth day, the tube was removed; the respirations at once became slightly stridulous with paroxysms of coughing which continued almost incessantly for two hours, the child dying of exhaustion. An examination of the trachea after death showed a small irregular-shaped ulcer at the base of the epiglottis, corresponding to the upper end of the tube, also a somewhat larger one, oval in shape and extending through the mucous membrane and involving the cartilages, on the anterior surface of the trachea, corresponding to the lower end of the tube.

The second case was a child, two years and seven months of age, with a history of a hoarse croupy cough, with paroxysms of dyspnœa for twenty-four hours previous to admission, profuse sanguineous discharge from the nostrils; enlargement of the glands of the neck; diphtheritic membrane covered the tonsils, and on the inner surface of the lower lip was a large stomatitic or diphtheritic ulcer. The dyspnœa, which was moderate, became well marked on both inspiration and expiration twelve hours after admission, and intubation was performed. On the ninth day, the local evidences of diphtheria having disappeared, the ulcer of the lip being nearly healed and the general condition much improved, the tube was removed.

Its removal was followed by a violent attack of dyspnœa, necessitating its immediate reintroduction, the cough became more frequent, of a harsh laryngeal character with expectoration of thick yellow mucus, at times streaked with blood; there was a very fetid, almost gangrenous odor from the breath, and although the child was taking a large quantity of nourishment, rapid emaciation, and death from exhaustion occurred on the twenty-fifth day of the disease.

The third case was a child five years of age, with a fading rash of scarlet fever at the time of admission, enlargement of the glands of the neck; thin watery discharge from the nostrils, and diphtheritic membrane covering both tonsils, and lining the anterior nares. Intubation was performed on the sixth day, or two days after the first appearance of the laryngeal symptom; the case progressed favorably, and on the tenth day, all evidences of diphtheria having disappeared, the tube was removed. The removal of the tube was followed as usual by slight stridulous breathing, which passed off in a few hours, and the child seemed in a fair way to convalescence, but a harsh laryngeal cough suddenly appeared, with expectoration of frothy mucus, occasionally streaked with blood, very fetid odor from the breath, and in spite of a ravenous appetite, the child grew very weak and emaciated and died on the sixth day after its removal. In both of these cases, the symptoms were very much the same, and similar to what might be expected from a gangrenous ulceration of the larynx or trachea. Unfortunately an autopsy could not be obtained.

Another interesting case was that of a child, three years of age, suffering from a severe form of nasal and pharyngeal diphtheria with extreme stenosis of the larynx on admission. Intubation was immediately performed and the child improved rapidly, so that on the sixth day the diphtheria having entirely disappeared from the throat and nose, and the general condition being much improved, it was decided to remove the tube. In passing the finger over the base of the tongue preparatory to introducing the extractor, there was an intense spasm of the glottis, the face became blue, head drawn back, and the body rigid, with almost complete cessation of respiration; the gag being still in position, an attempt was made to pass the finger into the larynx, but it was impossible on account of the constriction of the throat; this passed off in a few seconds and the tube was quickly removed. The respirations at once became stridulous, and before the tube could be prepared for reintroduction there was a second spasm more intense than the first, with complete cessation of respiration; this also passed off in a few seconds, the muscles became relaxed, face pale, the child gasped several times and began to respond to efforts at artificial respiration. The patient, still unconscious, was held in the nurse's arms and the tube easily introduced, artificial respiration being continued for several minutes before the child became conscious, when it was apparently as well as before the tube was removed. On the thirteenth day the tube was again removed, this time without any difficulty, the child breathing quietly for about five minutes, when the respirations became stridulous and immediately followed by a spasm similar to the one on the sixth day. As the respirations continued very stridulous and labored, an attempt was made to reintroduce the tube, with the same result as before, the spasm lasting, however, much longer, so that when the tube was finally introduced the child was moribund and died in a few minutes.

This case differed from others in which the removal of the tube was followed by violent dyspnœa, in that the passing of the finger over the base of the tongue seemed to excite a distinct spasm of the glottis very similar to that seen in laryngismus stridulus.

In three cases of severe diphtheria, with nephritis, dying from the effect of the septic poisoning, in which slight dyspnœa was present, the tube was removed and found to be nearly filled with thick mucus and cheesy material, the patients breathing easily and naturally after its removal, without any return of the dyspnœa.

The average age was two years and eleven months; youngest nine months, oldest seven years. In twenty-five cases admitted with diphtheria in which a fairly accurate history was obtained, the day of the disease varied from the second to the ninth, the average being the fourth.

Swelling of the glands of the neck was marked in twenty-eight, slight in eleven, and absent in three cases.

Discharge from the nostrils was slight in six, marked in eight, sanguineous in eleven, and absent in seven cases, although membrane was present in the anterior nares in only thirteen. When present in the throat the membrane was confined to the tonsils in fourteen, to the soft palate in one, to the tonsils and soft palate in eight, and to the tonsils, soft palate, and pharynx in nine cases.

In the majority of cases it was found very difficult to

obtain a clear history as to the time of the first appearance of the laryngeal symptoms, *i.e.*, the croupy cough.

In twenty-five cases the time from the first appearance of the laryngeal symptoms to the introduction of the tube varied from twenty-four hours to eight days, the average being about four days.

Progress of Medical Science.

PULSATING TUMORS OF BONE.—A paper was read recently by Dr. MacDonnell, before the Royal Academy of Medicine in Ireland (*The British Medical Journal*, November 24, 1888), on pulsating tumors of bone. He detailed the case of a lady who had been sent to him by Mr. Erichsen, nearly five years before. She then suffered from a pulsating tumor over the upper part of the fibula, which he and Mr. Erichsen agreed in regarding as probably a hæmatoid sarcoma of the bone. It continued for some time to increase in size. Operation was delayed on account of the lady's pregnancy, but she was directed to wear an elastic stocking. She suffered after delivery from phlegmasia of the other limb, which caused her to remain in bed for nearly six months, still, however, wearing the elastic stocking. When she came again under his observation, some time after her parturition, the tumor had disappeared. The case, which the result showed to have been probably an osteo-aneurism, was of much interest as pointing to the difficulty of diagnosticating between osteo-sarcomata and osteo-aneurism. In this case the resemblance to the former disease was so marked that, but for the delay caused by the pregnancy of the patient, an operation (which the result showed was not necessary) would probably have been performed. In the discussion which followed, Dr. Mapother said his case (to which Dr. MacDonnell had referred) arose some twenty-six years ago, and there was a previous one treated by Mr. Bickersteth, of Liverpool. In his own, the patient, aged twenty-eight, got a knock on the shin, and four months afterward a tumor as large as a walnut formed, half of it projecting beyond the level of the tibia without discoloring the skin, while the corresponding portion went into the substance of the bone. There was a distinct distensile' pulsation, thrill, and *bruit*. Aided by Dr. Hutton, he removed the cuticle by potassa fusa, and then applied a cautery. After ten days intense hemorrhage occurred, as of a nævus suddenly wounded. In a few days the nævus matter came away, leaving a granulated surface, and rapid cure took place. Sixteen years subsequent to the operation he had heard of the patient as being alive and well in New Zealand. There was only a slight cicatrix, and thick bone around. Mr. Wheeler had seen two cases of pulsating tumors of bone, both sarcomata—one in the practice of Mr. Butcher, the other was in his own. In his own case, the seat of disease seemed to be the lower end of the tibia, which was distended. There was distinct *bruit*. He amputated at the knee-joint, revealing a tumor which Dr. Barker described as an osteo sarcoma. Eighteen months later the patient died of tumor in the liver, and he believed also in the spleen. He regarded Dr. MacDonnell's case as one of aneurism by anastomosis. He asked whether Dr. MacDonnell attributed cure to the rest and pressure the patient had while suffering from phlegmasia dolens. Mr. William Stoker said he had had a case of pulsating tumor started from the fibula, in a boy aged twelve. At first the tumor seemed localized to the shaft of the fibula so distinctly that he determined to remove the upper part; but the child's mother would not consent. Rapid distention having taken place, the child was brought back in a month, and the pulsation was notable, while the circumference of the limb had increased two inches in the interval. Although the rapidity of the distention made the result doubtful, yet he amputated above the knee, and the patient was now a young man alive and well. Dr. Phineas Abraham had pronounced the tumor to be a giant-celled sarcoma. There had been no recurrence. Mr. H. G. Croly called attention to the fact that the discussion had extended both to the subject of osteo-aneurism and that of malignant disease attacking the bone, while Dr. MacDonnell's paper referred to a case which was not malignant. So, too, was Dr. Mapother's case. Osteo-aneurism, it was agreed, was a disease that was not malignant, and the great interest in Dr. MacDonnell's case was the cure of the aneurism. He did not understand how phlegmasia dolens, even occurring in the same limb, could effect the cure. He had had a case of osteo-sarcoma in a girl aged eighteen, with a growth involving the lower end of the femur. Dr. MacDonnell concurred with him that her only chance was by amputation below the trochanter. The operation was performed, and she made a good recovery. After four or five years, however, she was attacked at the upper extremity at the opposite side by the same disease, which rapidly proved fatal. Dr. Ball said they had at present a case in Sir Patrick Dun's Hospital, in which the difficulty of diagnosis suggested by Mr. Croly presented itself, namely, of distinguishing between pulsating sarcoma of bone and pure angioma. On admission the patient complained of a small tumor on the top of the head, with intense pain in the back of his head and neck. The tumor was soft, and no pain could be detected in it; but very soon it enlarged, and the pulsation became marked, a train of cerebral symptoms developing apparently from pressure. He had periodical attacks of vomiting. Double optic neuritis and loss of sight ensued. Believing that if they arrested the blood-supply they might be able to retard the rapid progress of the tumor, he ligatured simultaneously the two external carotid arteries above the facial artery. The result was an amelioration of the symptoms; the vomiting entirely disappeared, the pulsation ceased, and the tumor decreased in size till it became imperceptible. However, now, at the end of a month, the symptoms were again developing—slight pulsation and severe pain in the head. There were veins as big as the little finger radiating round the skull, and the blood could be squeezed out, and a small hole detected where the communication existed. The case was one of angioma perforating the skull.

FRACTURE OF THE HEAD OF THE HUMERUS DUE TO MUSCULAR ACTION.—M. Auguste Pollosson has reported the result of his examination of two specimens taken from the body of an epileptic who died during a convulsion, and who had suffered no traumatism of any description. The upper articulating extremity of the humerus on each side presented lesions which, seen externally, were absolutely alike and symmetrically situated. These lesions consisted in a forcing in of the cartilaginous part of the humeral heads. The depression was found over the anterior part of the head near the border of the cartilage, immediately above the lesser trochanter; it had the appearance of a groove from two and a half to three centimetres long, and from five to six millimetres deep. The cartilage was bent toward the hollow of this groove, and presented near the deepest part a fissured line of fracture. A perpendicular section at the seat of the depression showed similar appearances. The laminæ of compact tissue beneath the cartilage presented the same curve and the same fracture. The lamellæ of the spongy tissue were broken and the spaces were infiltrated with black blood, evidently proceeding from an interosseous hemorrhage, and not from a congestive or inflammatory state. The lesions were similar on both sides. On the left humerus, beneath the inferior or lower edge of the groove, there was found a movable bony fragment of about a centimetre in diameter, surrounded with a bloody effusion. The bones were not diseased nor preternaturally brittle. The absence of traumatism, the symmetry of the lesions, and the evidences of hemorrhagic infiltration of all the shoulder muscles evidencing a spasm of great violence, were sufficient to explain the occurrence of this very rare accident.—*American Journal of the Medical Sciences.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 23, 1889.

CHRISTIAN SCIENCE AND MEDICINE.

WHEN, about eighty years since, an ingenious gentleman of Leipsic announced his discovery of the rational treatment of disease by the administration of drugs so attenuated that the patient scarcely obtained a fleeting smell of the medicament, he little thought that in the year 1889 the effects produced by his system would be so admirably explained by one of the laity as has been done by the Reverend Mrs. Eddy, of Boston, in a recent lecture delivered in this city, on the subject of "Christian Science as Applied to the Treatment of Disease." If we may believe the newspaper reports of this lecture, the reverend lady stated that, by actual experiment, she had found that a drug increased in efficacy as it was more and more attenuated, until its most happy effect was produced by its entire disappearance—a paradox explained by the fact that the mental power of the patient is the true active principle of the drug. Disregarding after this statement, the faint crepitus she might have heard, had her reverend ear been applied to the chest of mother earth produced by the bones of Hahnemann as he changed from a dorsal to a lateral decubitus in his sepulchre, she further remarked that this or these experiments had induced her to disregard the claims of materia medica to recognition as an exact science. The latter statement must have been misunderstood by the reporter, or have been toyed with by the type-setter; for no expounder of a scientific system of medicine, or rather a substitute for it, could have made the error of saying materia medica when therapeutics was meant. Therefore, holding the opinion that disease is but the shadowy creature of a perverted mind, one which is able to breed tubercular bacilli or gummy tumors at will, it is to be assumed that the Reverend Mrs. Eddy has made herself thoroughly acquainted with theoretical and practical pathology, and, indeed, with all branches of the pseudo-science she contemns; and, as one eminently proficient in the mathematically exact sciences of Theology and her own cherished Christian science, she would never conscientiously believe, or state in public, conclusions which were not drawn from data she personally had gathered by her own observation and exhaustive research. We have too much respect and reverence for the profession of which the followers are entitled to the adjective which Mrs. Eddy bears before her name, to believe for a moment that any minister of the Gospel of Christ would make erroneous statements as to facts intentionally or upon insufficient grounds. And yet it seems strange that when a patient, who has a fever so active as to cause continuous delirium, recovers without loss of flesh and strength because he was not aware of his illness on account of his delirium, and that another man, afflicted with fever "of the same kind," but unaccompanied by delirium, is much weakened and emaciated at the occurrence of defervescence as a result of his belief that his fever had a definite course to run, and was certain to produce a weakened condition of the system, the reverend lady should hold that the disease was the offspring of the mind, whether said mind was so actively employed in its work of creating and keeping up the disease as to be ignorant of everything else, or, indeed, of its own employment, or was normally cognizant of external matters and of its own labors in the interest of the disease. Unless her words have been sadly distorted by the reporters, such must be her belief, and the treatment in either case must be by adding faith to your will, even when the same will is absent on an expedition having for its object the gathering of wool, or is employed in "babbling of green fields." Does the Reverend Mrs. Eddy believe that the mind or will which has its seat in a softened brain, or which vegetates in the cerebrum of an idiot, or riots in that of a maniac, can "rise above matter and come nearer to God," when the possessor is either gasping for breath during the second stage of a double pneumonia, or is lying in the coma vigil of typhus fever? Is the fact that occupation of the mind will cause one to forget the pain of a nervous headache, in certain instances, any reason why the employment of airy *persiflage*, or entertaining conversation, should be considered a specific in the treatment of acute meningitis? Is there no actual difference between the ophidian usurper of the lawful kingdom of the foot of a patient who is absorbed in the zoölogical ecstasy of *mania à potu* and the clammy, sedentary tænia solium?

These are pregnant questions, but we fear that we have groped in darkness which can be felt for all these years, during which the lives and energies of deluded *savants* have been wasted in pathological research. Why then wrangle over early or late incision for perityphlitis, or over electricity or myomotomy for uterine fibromyoma? Do not take instruments for the performance of tracheotomy or intubation when you are called to a case of diphtheritic laryngitis—for the little sufferer only thinks he cannot breathe—but sit down and tell him so, at the same time mentioning the doctrine of justification by faith, or relating the parable of the eleventh-hour workers in the vineyard. Do not bother a new-born baby by cleansing its eyes when it believes them to be affected with purulent ophthalmia, but tell it how to rise above matter (which is very easily located at such a time), and how to concentrate its infant faith on things higher than this life, and of the Spirit.

The miracles performed by the Saviour seem to form the principal foundation of Mrs. Eddy's system of cure; at least she considers His example as the one we should adopt in our efforts to relieve human suffering. Does she remember the statement made by Him when Satan suggested a leap from the lofty summit of the highest tower of the Temple: "Thou shalt not tempt the Lord thy God." How does she, after rising above matter, and becoming independent of all disease, expect

to unloose the silver cord and break the golden bowl? If after the method of Elijah, will she drop her sealskin dolman and resign her percentage of the profits to some intimate friend, or will she simply vanish into thin air? And, by the way, if faith can remove mountains, and concentration of mind overcome the wear and tear of life on heart, brain, and muscles, why not on purple and fine linen, so that Easter-bonnets will be perennial? Would not much more profit, and more proselytes, be made if the reverend lady would, in a moment of leisure, lend her faith to M. de Lesseps, and at the same time neutralize the deadly miasma of the Chagres fever at Panama? Certainly some such work is better, more Christian and scientific, than occupying the presidential chair of a college in Boston, or making a number of no matter how iconoclastic, empty, unsupported statements to a paying audience in Steinway Hall. The life or health of many a poor wretch would be saved; the prosperity of many nations would be increased, and the cause of Christian science would be triumphant.

We feel that this advice is most generous on our part, for we earn our bread by the sweat we produce on the brows of our deluded patients, provided they are pleased to make practical demonstration of the gratitude they profess when first emerging from the gloom of what they, and we, have believed to be the Valley of the Shadow of Death, but which the Reverend Mrs. Eddy says is only the fictitious umbra of the infidel turpitude of an unregenerate mind producing an eclipse of the bright luminary, faith, because no attempt has been made to rise above matter. But even we, if by any means the health and prosperity of the community be improved, will cheerfully exchange our hypodermatic syringe for an unctuous and esoteric vocabulary, and our contributions to THE MEDICAL RECORD for subscriptions to the *Evangelist*.

The medical profession is not of the Scribes and Pharisees, but rather of the Thomas bent of mind—it does not refuse to believe, but only doubts, in order that it may believe; and when the marvellous cures attributed to Christian scientists are authenticated by testimony a trifle more valuable than that of the same class of people, who report rapid cure "of what all my friends said was a cancer," by the consumption of so many bottles of this or that patent medicine, the great majority of the physicians will be content with what of substance they may extract from the Gentiles, who will cling to the castor-oil and quinine of their ancestors.

SPORADIC CEREBRO-SPINAL MENINGITIS.

EPIDEMIC cerebro-spinal meningitis was first observed at Geneva, in 1805. The very next year it developed in Massachusetts, and during the next ten years it spread throughout New England. It was during this period that an American writer, Dr. Gallup, gave an excellent account of the disease as it appeared in Vermont. His place of residence, Woodstock, was the centre of an extensive epidemic. It seems to be a fact that, when the disease has once appeared in a place epidemically, it leaves certain slumbering germs which every now and then cause the appearance of sporadic cases. This is true of Philadelphia, where the disease has been endemic since 1863; and of New York, where we find cases reported almost continually since 1861. In country districts this rule seems also to prevail, if we may judge from the accounts given by Dr. F. T. Kidder, of Woodstock, Vt., where the disease was once so virulent. Dr. Kidder reports the case of a young lady who, without any known cause, was suddenly attacked with a severe chill followed by a fever temperature ranging as high as 103°. The patient suffered from terrific pains in the back of the head and neck, hyperæsthesia, spinal rigidity, and a tendency to opisthotonos. The fever and other symptoms lasted for two weeks, the patient's condition becoming most critical. After this, gradual improvement set in. A relapse, or second attack, occurred at the end of three months, and a second relapse some months later.

The fact that a latent endemic infection may exist and occasionally give rise to its special disease, is one that it will be well to bear in mind. Dr. J. Lewis Smith has suggested that some of the obscure forms of paralysis in children may be abortive manifestations of cerebro-spinal meningitis; and that neuritic pains and paralyses may have the same origin is not improbable.

It may be noted in this connection that cerebro-spinal meningitis is somewhat more frequent in this city at present than usual, from two to five new cases being reported weekly. As nearly all the cases reported have died, it is probable that a number of cases exist of which the returns have not been sent in.

RECENT STUDIES OF AMYLOID DEGENERATION.

THERE have been a number of contributions during the past two years to the subject of amyloid degeneration. The works of Labadie-Lagrave and of MM. Lecorché and Talamon may in particular be cited. Dr. A. B. Martin has given an interesting review of these in a recent article in the *Gazette des Hôpitaux*. Some of the critical observations there made we propose to give to our readers.

Amyloid degeneration occurs only in persons who have suffered from a prolonged cachexia. All forms of cachexia, however, do not cause this degeneration. The three principal types are those of chronic tubercular processes, syphilis, and prolonged osseous suppuration. This degeneration is also sometimes observed in empyema, chronic bronchitis, old ulcers, chronic pemphigus, malignant variola, dysentery, and phosphorus necrosis. It is a striking fact that in all these forms of trouble except syphilis, suppuration exists, and the fact lends weight to the theory that the syphiloma, as well as the tubercular tumor, are only modified or abortive forms of the suppurative process.

Amylosis, however, is also said to occur sometimes in chronic rheumatism, gout, malaria, and alcoholism. MM. Letulle, M. Moutard-Martin, and others have asserted that this same degenerative process may accompany, and perhaps be caused by, arterio-sclerosis.

Most interesting of all is the fact established by Charrin, that the *bacillus pyocyaneus* can cause in certain lower animals a peculiar disease known as the *maladie pyocyanique*. In this disease the animal suffers from paralysis, nephritis, and, finally, amyloid degeneration.

It has long been known that the so-called amyloid material is in reality not a carbo-hydrate, but a nitrogenous body. There has been much dispute, however, as to

whether it was carried in the blood and deposited in the degenerated organs, or was formed in these organs. The experiments of Charrin seem to show, if no other proof were at hand, that the latter theory is the more correct one. It seems at the present time probable that the degeneration results from the irritation of a specific poison, generated by suppurative or pyocyanic micro-organisms, and carried in the blood to the affected parts.

It would be natural on this supposition that eliminative organs like the kidneys should be especially affected, and also that the poison destroying organs like the liver should be affected by the process. The same hypothesis would explain also the amyloid degeneration of the vessels in which the diseased blood circulates.

Amyloid degeneration of the kidneys may be complicated with interstitial nephritis, forming the small white kidney (Lecorché and Talamon), or with cystic or tuberculous processes; or the waxy change may exist alone.

The symptoms produced by amyloid degeneration complicated with nephritis present nothing distinctive. The pure amyloid kidney has, however, a quite characteristic and well-recognized clinical picture. The urine is abundant, pale, of light specific gravity, and contains a small amount of albumin. Senator asserts that there is a peculiar form of albuminuria, viz., paraglobinuria. This is denied by Petri and Heyusius. One finds hyaline casts in the urine which are not, however, amyloid in character. Dropsy and uræmic symptoms are rare.

The treatment of amyloid degeneration is not very encouraging. After removing the cause of the suppuration and cachexia, if that can be done, very little remains for the therapeutist. An organ once degenerated can probably never be restored. If the suppurating focus cannot be cured, its poisoning effect must be offset as much as possible. We may, in time, discover some antidote to the microbic irritant that turns good tissue into useless wax. The *bacillus pyocyaneus* may even furnish us a help, used in attenuated cultures.

WASHING OUT THE STOMACH IN INFANTS.

WASHING out the stomach is now practised quite generally in a number of gastric derangements, and this method of dealing with morbid states of the stomach has steadily grown in favor for the past few years. Of late this practice has also been extended so as to include infants' diseases, and a number of favorable reports have been made relative thereto. One of the most important contributions to the subject yet published, was made recently at Berlin by Dr. Leo. *The Medical Press* has referred at some length to the address delivered by this observer, and the subject appears sufficiently interesting to warrant our transcribing *in extenso* the remarks of our contemporary. It is stated that Dr. Leo had followed out the practice in one hundred and thirty-four infants in Senator's Poliklinik. For determining the normal condition, he made use of thirty children between the ages of two hours and twelve months. He remarked that after the introduction of the œsophageal tube the contents of the stomach were generally evacuated spontaneously. It would be remarkable, indeed, if they were not. The reaction of the contents of the stomach immediately after taking food was neutral, or slightly alkaline in the case of breast milk, but with cow's milk it was slightly acid or neutral. A quarter of an hour after it was distinctly acid, within an hour after taking food no free acid could, as a rule, be detected, but it was almost always present in the fasting state. The free acid was hydrochloric, but lactic acid was also sometimes present in small quantities. No volatile fatty acids were ever met with. Pepsin was almost always found, whether the stomach was empty or full. Curdling ferment was always present in the stomachs of the newly born, and was independent of the presence of hydrochloric acid. The quantity of curdling ferment was frequently so great that milk coagulated, even in the cold, in a few minutes. The contents of the stomach were generally freely mixed with mucus, frequently brown streaks were found, being the residue of blood swallowed during birth. Investigation showed that a considerable portion of the milk had passed out of the stomach in half-an-hour. The time at which it had all passed out varied with the age of the child and the kind of nourishment. In younger children the stomach was frequently empty within an hour, but in older children more time was required. When cow's milk was the food employed it had not all passed out in an hour and a half, but it had invariably done so within two hours. If at this time the stomach was free from nutriment, it could not, however, be said to be absolutely empty. Only a few drops of fluid could be collected at this time, but they contained all the characteristic constituents of gastric secretion.

The practical observation was made by Dr. Leo that digestion in the stomach is not the same thing as digestion outside of it. In the stomach, fresh acids being continuously secreted and mixed with the digestive fluids, they would thus exert their influence upon them. This they could not do outside the stomach. The author also found that only slight solution of the casein had taken place in the incubation chamber in twenty-four hours, which of course bore no relation to the processes going on in the stomach. His method of examination was the following: A certain time after the child had taken the breast the contents of the stomach were brought up again, and examined for the contained peptone and propeptones, and the result compared with a sample of the food taken that had been made to curdle. After the milk was in the stomach for half an hour there was distinct increase of the first and second propeptones. Peptone itself was only present in small quantities. After an hour the quantity of peptone and of propeptones had considerably increased. Peptonization of milk therefore took place in the stomach. By this it was shown that continuous secretion of hydrochloric acid took place in the stomach. Peptonization of milk in the stomach was not of great importance as regarded digestion. This is owing to the short time the food remains in the stomach, digestion being mainly performed in the small intestine. The influence exercised in the stomach on the micro-organisms present in the salivary secretion seemed to be important, as the development of a part of them was arrested.

After these interesting and important physiological observations, the author proceeds to give his clinical experience with sick children. One hundred and four cases constituted his working material. Of this number sixty had dyspepsia, twenty-two suffered from cholera infantum, sixteen from subacute or chronic gastric catarrh, and six

from diarrhœa without loss of appetite. In regard to the reaction of the contents of the stomach, it may be remarked that whether full or empty it was acid, except when the food was breast milk. In many cases it was abnormally so, and dependent on volatile fatty acids, butyric and acetic as well as lactic acids. The disagreeable odor of vomited matter was due to butyric acid. Sometimes the amount of hydrochloric acid was abnormally large. Pepsin was generally to be found, but curdling ferment always. The constant presence of this explained why when cow's milk was given it was always found to be curdled.

One of the most salient features of all gastric affections is the abnormal length of time that the milk is retained in the stomach. In a case of acute febrile dyspepsia a considerable quantity of food of acid reaction, and containing volatile fatty acids, was present seven hours after it had been taken. A similar thing occurred in many cases of diarrhœa. It is plain, therefore, that in these cases there was deficient motor activity of the stomach; not, however, as a cause, but as a consequence of the illness. This was shown by the fact that after recovery and appetite had returned for several days this abnormal delay of the food in the stomach could be determined. A considerable quantity of tough mucus was particularly met with in gastritis and dyspepsia. Considerable quantities of gas were also observed to escape on passing the tube, especially in cases of gastro-ectasis.

In relation to the therapeutics of the subject, Dr. Leo noted two points. First, that the investigation explained why hydrochloric was of no value in many cases, and sometimes caused pain; and secondly, the uselessness of pepsine. But the value of clearing out of the viscus all noxious material gained new support from his investigations.

The fact that many practitioners were averse from carrying out the practice in children led him to relate his own experience. The method consisted in passing a soft sound, with funnel attached, into the stomach, and the employment of some washing-out fluid. Scarcely any difficulties were encountered. It was generally easier of performance in infants than in adults. He only occasionally observed retching movements, stoppage of the breath, and cyanosis, but never unfavorable consequences. He used simple water for washing out in many cases, but latterly a few drops of a twenty per cent. alcoholic solution of thymol. As food he ordered pure or diluted milk, or milk mixed with oatmeal gruel, and when infants are at the breast he does not interrupt the feeding. The results were, on the average, very good. In many cases repeated washing out was required, and was frequently done for a week or more. The best results were obtained in acute dyspepsia with or without vomiting or diarrhœa. A single washing out often sufficed for complete cure. In many cases there was high fever that vanished after the washing out. The results were much less pronounced in cholera infantum. Of 22 cases, 10 recovered after one or more washings, 6 were influenced by the treatment, while 4 did not return after the first washing. He also obtained good results in acute or chronic dyspepsia with intestinal trouble. Cases of habitual vomiting and severe diarrhœa were improved. It was a method of treatment not to be put into practice indiscriminately. The principal indication for it was dyspepsia. It was of more extended use in children than in adults.

THE OLD BOTANIC GARDEN.

In view of the proposed new Torrey garden, concerning which so much has been said of late, and to which allusion has been made in these columns, a few words of history may not be amiss concerning the old garden, which in its day enjoyed considerable prominence. It occupied the land west of the Columbia College buildings, and was owned by Dr. David Hosack, who purchased the ground from the city. From the Scottish birthplace of his father, it was named the Elgin Garden. From illustrations given in periodicals of that day, it must have been quite an imposing affair, containing, as it did, the area of four large city blocks.

The object of the owner, primarily, was to collect and cultivate native plants, especially those possessing medicinal virtues. In 1805, some fifteen hundred species of native plants were under cultivation. The collection was gradually enlarged, and reached its greatest value about 1811. The ground was covered with suitable buildings. A substantial stone wall, lined by a belt of forest-trees and shrubs, surrounded the premises, which were one of the sights of the city.

Naturally, the maintenance of such an establishment was very expensive, and soon outstripped the private means of its owner. He proposed to sell it to the State, the latter to maintain it for purposes of instruction, especially in medical study. Accordingly, in 1810 the Legislature consummated the bargain for about seventy-five thousand dollars, and the garden was placed under the formal charge of the Regents of the University.

The latter had no money to devote to the support of their newly acquired property, and placed it in charge of the faculty of the College of Physicians and Surgeons. The latter body was to maintain the garden according to the original intent, under the inspection of the regents. The garden proved an elephant on the hands of the college authorities. The expenses of keeping up the hot-houses, heating apparatus, drainage, etc., were great. It had great trouble with the gardener in charge. The property gradually ran down. It was too far, in those days of no street cars, or elevated roads, from the medical teaching centre, which was in Barclay Street. In a word, it died out, and in 1816, under legislative authorization, Columbia College became the owners, for some consideration unknown. The valuable plants remaining at the time were given to the Bloomingdale Asylum. Of the value of the land, at this time, Munchausen tales might be told.

Of the whole transaction, we might say after this lapse of years, "'tis true, 'tis pity," etc., but we must not judge too harshly. It seems somewhat strange that the State did not provide, in part at least, for its maintenance as well as wholly for its purchase. The great extension of the municipality northward would have, of course, long ago necessitated its removal, but it seems a pity that the present generation is obliged to duplicate, at a greatly increased expense, the work of four-score years ago. The idea of instructing medical students in the botany of native medicinal plants is a highly commendable one, but must, in the present state of science, be thoroughly systematic, and be associated with laboratory work. This will be practical botany from beginning to end. The work must be

required, not merely permissive. If the new garden shall be established, and we sincerely trust it will, we doubt not but that its teaching facilities will be freely placed at the disposal of our local institutions of learning.

News of the Week.

DR. HUME'S CASE.—Dr. William A. Hume writes: In the report of a case of compound depressed fracture of the skull, in the last issue of THE MEDICAL RECORD, the date 1886 should be 1881. The duration of the case was over seven years, which, considering the extent of the lesion, adds to its interest. Kussmaul and Fenner should read Kussmaul and Tenner. The diagram should be reversed."

DR. J. J. MULHERON has retired from the editorship of the *Medical Age*. He is succeeded by Dr. B. W. Palmer.

ESCHSCHOLTZIA CALIFORNICA—A SUBSTITUTE FOR MORPHINE.—The Paris correspondent of the *New York Medical Journal* reports in a recent number that M. Bardet and M. Adrian have examined the American plant called *Eschscholtzia Californica*, and they find that it really contains morphine, and this is the first time that a plant of any other order than the *Papaveraceæ* has been found to contain that alkaloid. Dujardin-Beaumetz says of it: "*Eschscholtzia Californica* is a soporific of great value, while its use is unattended by untoward effects. It is an analgesic of much worth in certain cases. It does not present the inconveniences of morphine, while its administration is very simple. The dose administered has been from 2.50 to 10.0 grammes per day, and it can be given either as a decoction, a syrup, or in the shape of pills.

THE AFRICAN HYMEN.—Controversies of a curious and unique character often arise in scientific circles. None is more curious than that concerning the position of the hymen in the negro race. The late Dr. Turnipseed, of South Carolina, used to claim that the hymen in the negress was not over but above the vaginal entrance. This he claimed to be a natural and providential race-distinction (Dr. E. S. McKee, *Annals of Gynæcology*). This view is controverted by Dr. Hyatt, of North Carolina, who has had the tropical experience of examining one thousand virgin negresses, and finds the hymen having the same relations as in the white race.

A MUNIFICENT DONATION.—By the will of the late Alexander Murray, of Montreal, the Montreal General Hospital will come into possession of the sum of $750,000. Next to the donation of $1,000,000 made by Sir Donald A. Smith and Sir George Stephen for the founding of the Royal Victoria Hospital of Montreal, that of Mr. Murray is the largest ever made in Canada for any similar purpose.

AN INTERNATIONAL MEDICAL ASSOCIATION.—With a view to promote social intercourse and maintain good fellowship between British and American physicians who practise on the Continent, it is proposed to form a society under the title of the British and American Continental Medical Society. The membership is to be limited to British and American subjects who are actually engaged in the practice of medicine abroad.

CRIMINAL ABORTION BY BLOWING AIR INTO THE UTERUS.—Dr. S. B. Ward, of Albany, reports the case (*Albany Medical Annals*) of a woman three months pregnant, who introduced a catheter into the uterus. Her paramour then blew air into it. The woman uttered a cry, sank back unconscious, and in a few hours died. Dr. Ward testified that death was caused by shock, no air being found in the circulatory system. The incident recalls the reputed fact that a notorious female abortionist of this city used to produce abortions by inflating the uterus with air.

THE HOMŒOPATHS OF NEW HAVEN are trying to get money to build a hospital. It is asserted that half the property in New Haven is owned by homœopaths.

A FAMINE OF CASCARA SAGRADA is reported. The habitually constipated, however, need not feel distress as long as *ricinus communis* continues to bloom, the *aloe socotrina* to exude its juice, and the cathartic springs of Europe to pour forth their healing streams into the bottles and barrels of their bloated and eupeptic stockholders.

SPINAL SURGERY.—Dr. Robert Abbe has recently trephined the spinal canal for a second time, opened the dura, and resected the posterior roots of four nerves in a case of intractable brachial neuralgia and neuritis. The patient is reported to be doing well.

CHEEVER SCHOLARSHIP.—The Harvard Medical School has just received from Dr. D. W. Cheever the sum of $5,000 to establish a scholarship, to be known as the David Williams Cheever Scholarship.

MUST NOT HAVE SPECIALTY ON CARD.—The American Association of Genito-Urinary Surgeons says that it will not consider the application for membership from one who on his card states that he is a Genito-Urinary Surgeon. He can do this in connection with his papers in medical journals, and with the reprints of the same, in the announcements of the dispensaries, etc., with which he is connected. By these means he may advertise his specialty among the people and the profession, but he must not do the same thing with his cards.

VETERINARY MEDICINE AT HARVARD.—President Eliot, in his annual report, does not speak encouragingly of the Veterinary Department. It is justly said that this "department should be made a centre of research in the many fields where the health and well-being of men and animals are bound up together," but the continuance of an annual deficit makes it doubtful whether there is sufficient interest in the school to secure an adequate endowment.

A MINISTER OF PUBLIC HEALTH FOR FRANCE.—The Sanitary Department in France was formerly attached to the Ministry of Commerce. This was natural when French sanitation was confined to enforcing measures for preventing the propagation of epizootic diseases. This connection has recently been severed, and the Sanitary Department has been attached to the Assistance Publique of France. M. Monod (whose reputation as an enlightened sanitarian is established throughout Europe) has been nominated by presidential decree director of the two services, with the title of Director of the Health Service.

CROWDS OF AMERICAN MEDICAL STUDENTS.—The number of Americans attending clinics and lectures in Vienna appears to be increasing from year to year. The practical courses given by the "Privatdocenten" are the most popular. The Americans are always eagerly welcomed by the teachers in the various special departments, on account of the extra fees that many of them bestow. "Crowds of students of medicine" are getting to be a well-recognized social phenomenon all the world over. Where they all come from, and what becomes of all of them, is still apparently enveloped in mystery.

TOO MUCH OF A GOOD THING.—It is reported that the accommodations for both students and patients in the clinical service at Vienna are wholly inadequate to the demand upon them. There are so many patients that they cannot receive the attention necessary for the treatment of their complaints and cannot be satisfactorily utilized for purposes of instruction, and the crowd of students is so great that none of them is able to derive much benefit from attendance at the clinics.

MASSAGE IN THE PACIFIC ISLANDS.—In a recent number of the *Glasgow Medical Journal* Dr. Anderson writes: "From time immemorial the practice of massage has been known to the Fijians, from whom the Samoans first, and then the Tongans, learned the art. The process consists in rubbing and kneading the part, the operation being sometimes continued for hours; it stimulates the circulation and relieves pain, and is commonly used in abdominal disease. The native doctors have great faith in massage, and it is always practised by them."

A STRANGE ACCIDENT.—A medical student, named Grieme, who was acting as assistant to Dr. P. S. Conner, in the Cincinnati Hospital, was recently severely burned. He was heating a platinum knife by means of a lamp and a bottle of benzine, the latter being fastened to his waist by a belt. By some accident the benzine took fire and exploded, enveloping the unfortunate man in flames which were with difficulty extinguished. Mr. Grieme was very severely burned, but it is hoped that his injuries will not prove fatal.

ARSENIC POISONING.—A family party, consisting of the father and four children, narrowly escaped death by poisoning, recently, in a village in England. In the absence of the father and mother, the children made some pancakes for breakfast, mixing what they took to be soda, but which was in reality a paper of arsenic mixture, with the flour. After the father and children had partaken of the pancakes, they soon exhibited symptoms of poisoning and became violently ill. A neighbor who was called in administered an emetic, which took effect, and medical assistance was afterward rendered by Dr. French. The father and children are progressing favorably.

THE ACTION OF ANTIPYRETICS ON TISSUE METABOLISM.—Dr. Muneo Kumagawa, working in the chemical laboratory of the Pathological Institute at Berlin, comes to the conclusion, from experiments on dogs, that all antipyretics, except quinine, increase nitrogenous excretion. Antipyrin affects this process very little; the remaining drugs, viz., benzoate of soda, benzoic acid, salicylate of soda, salol, antifebrin, and thallin, all increase tissue water.

A CASE OF LEPROSY CURED.—Such is the title of a paper published by Dr. Dreckmann, of Vienenburg, in the *Monatshefte für praktische Dermatologie*. The patient, a man, aged forty-two, had suffered from *lepra mutilans* for four years, all his extremities being characteristically affected. He was treated by "Unna's Method," being painted with pyrogallic and chrysorobic acid salves, and salicyl-creasote plaster-mull. Internally he was given ichthyol. Most extraordinary improvement in all the symptoms followed, and eventually the patient became practically well.

BOOKS AND BACILLI.—From an experimental investigation carried out by the Dresden municipal authorities it would appear that pathogenic micro-organisms do not thrive on books. The dust from a number of unused volumes was found to be only matter of a harmless character. The tubercle bacillus was specially sought, and, most conspicuously, not found. The conclusion arrived at was that the danger of circulating libraries spreading infection is very slight, but a recommendation is given to dust books well before reading them, and never to wet the finger in the mouth for the purpose of turning over the leaves.

HOSPITALS IN THE STATE OF NEW YORK.—The incorporated hospitals of the State number sixty-five, of which fifty are general, and fifteen special in their objects. The property held by the hospitals, October 1, 1888, was valued at $14,045,551.00, as against $13,350,826.58, their valuation, October 1, 1887. Their receipts for the fiscal year ending September 30, 1888, were $2,601,174.75, and their expenditures, $2,203,921.74. The number of patients in their care, October 1, 1888, was 3,686, as against 3,516, October 1, 1887.

THE POST-MORTEM WARTS, says Dr. Wm. Osler, are now pretty generally regarded as local tubercle, the result of inoculation. The presence of bacilli has been demonstrated in several instances. The tubercles consist chiefly of granulation tissue, occasionally with giant-cells, and with papillomatous outgrowths of the epidermis, which give the tubercle the wart-like character. They are met with in persons who perform many post-mortems and in those whose business brings them into close contact with animals and animal products. Their occurrence is by no means infrequent. In Germany it is quite common to see the hands of the demonstrators of pathology (and more especially the attendants in the autopsy-rooms) disfigured by these structures. Mr. Hutchinson considers these warts a form of lupus.

WHAT BECOMES OF MEDICAL GRADUATES?—Sir James Paget made an inquiry some time ago into the career of one thousand medical graduates. Lately, says the *British Medical Journal*, the Dean of St. Mary's Hospital Medical School, Mr. G. P. Field, has occupied himself by tracing the careers of students educated at his school. He found that 1,000 men had joined the hospital up to last May, of whom 284 are present students, so that 716 had to be accounted for in other ways. Of these 716, 17 had left the profession, and 171 had been lost sight of altogether, some probably having also left the profession, and others having doubtless died. In addition to these, 64 were known to be dead, and 12 had failed entirely. These numbers (17, 171, 64, 12) added together amounted

to 264, and left 453 (63.2 per cent.) in practice. Of the 453, 371 were in general practice (231 in the country, 99 in London, 31 abroad, while 10 were dentists), 48 were in the Army and Navy, and 34 had achieved the great success of being on hospital staffs as teachers, or were distinguished in various other ways (14 had been elected on the staff of St. Mary's Hospital, 9 were on the staffs of other hospitals, and 11 others were distinguished men). Thus, according to Mr. Field's figures, about 34 of 716 students, or less than five per cent., achieved distinguished success. Sir J. Paget's figures give only 2.3 per cent. for the same class; but then he seems to have limited himself to fifteen years of practice, whereas Mr. Field's observations in some cases must have extended over thirty years, which may account for the difference, as distinguished success comes to some men only after tedious waiting.

THE THIRD RUSSIAN MEDICAL CONGRESS was held in St. Petersburg on January 15th and seven following days. It was opened with considerable solemnity, and in the presence of a large number of the political, medical, and scientific celebrities of St. Petersburg, by Professor Botkine, who said that the number of members present at the first Congress was 500, at the second 1,000, and at the third 1,500. Dr. Erissmann, Professor of Hygiene at Moscow, was elected President of the congress. The congress was divided into no less than eighteen sections, and an immense number of papers were read; to some of these we hope to refer in future. An exhibition—resembling in its scope the annual museum of the British Medical Association—was organized, and remained open for three weeks; it was especially remarkable for the historical collection of plans and models illustrating the development of hospitals in Russia.—*The British Medical Journal.*

THE JOURNAL OF OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY, is the title of a new quarterly journal edited by Drs. D. Geo. S. Norton and Chas. Deady, and published by A. L. Chatterton & Co., of this city. It is to be devoted chiefly to original articles.

THE MICROBE OF MALARIA.—At a recent meeting of the Academy of Sciences, Professor Bouchard presented, in the name of Professor Laveran, of Val de Grâce, a memoir on the parasite of impaludism. The parasite brought to notice by the author in 1879 is considered as being incontestably that which produces intermittent fever. Everywhere where cases of fever were examined the same organism was found, and that not only in France, but also in Germany, in Italy, in Russia, in Algiers, in Madagascar, etc. M. Bouchard, therefore, considers it as demonstrated that intermittent fever is due to the parasite discovered by Dr. Laveran.—*The Lancet.*

PROGRESS IN MEDICAL LEGISLATION.—The Supreme Court of the United States has decided that medical registration and licensing laws enacted by the States are constitutional. The *Epoch* says: "In at least three of our most populous States—New York, Massachusetts, and Pennsylvania—bills have been introduced into the Legislature with the express purpose of making all who wish to practise medicine submit to an examination before a State Board of Examiners. Of course such measures are vigorously opposed by the 'cancer' doctors, 'faith-curists,' magnetic healers, and all other quacks that feed upon the credulity of the public. The war between the 'regulars' and 'non-regulars' seems to be exceedingly vigorous in Massachusetts. According to one newspaper account the 'unprofessionals' have there raised a large amount of money to defeat any legislation designed to exclude them from practice. No good reasons have ever been advanced why all who wish to become doctors should not pass a thorough and strict examination before they are permitted to practise."

CYCLING AS A THERAPEUTIC AGENT has a considerable future; it ought not to be taken up at too early an age; the so-called "bicycle back"—round, stooping shoulders—is particularly liable to be produced in a growing lad who uses the bicycle too much; a convenient rule is to avoid recommending it till a lad has passed the age when the chief growth in height takes place. Dr. Jennings' book confirms the impression formed from observation and the perusal of scattered notices in fugitive literature, that cycling is a form of exercise specially useful to men who are growing to be a little more than middle-aged. A man who has followed a sedentary occupation begins to experience increasing disinclination to exertion, chronic constipation, with some stiffness and it may be flying pains in the joints; for such a man a tricycle is capable of accomplishing a great deal; exercise ceases to be a trouble, the bowels become more regular, and the joint troubles, which may be at first a little aggravated, disappear. Dr. Jennings believes that chronic gout and rheumatic gout may thus be cured, or at least kept at bay, even when the patient has been seriously crippled by several attacks; he also speaks very confidently as to the cure of obesity, if the patient will refrain from gratifying the thirst, which is at first very trying; he even finds some reason to believe that his favorite exercise may be a useful adjuvant in the treatment of early phthisis.

POISONING FROM SULFONAL.—The Berlin correspondent of the *Medical and Surgical Reporter* is responsible for the following: The new drug is, however, by no means so harmless as has been hitherto asserted by its manufacturers. Dr. Bornemann has just reported a case of severe poisoning resulting from the administration of the drug. The patient, to whom sulfonal was given for insomnia caused by cerebral excitement, was a physician. The result was a pronounced intoxication showing very complicated symptoms. There was a distinct interference of co-ordination, first in the lower and later in the upper extremities. He could not, for instance, raise a cup of coffee. A very prominent feature of the poisoning was his perverted feelings and illusions. The patient believed he had two heads, four feet and arms, etc.; or he believed he was on a boat or in a railway-car, and that someone was about to kill him. These illusions may be termed reflectory. The ataxia referred to is a central one, as it remained unchanged no matter whether the eyes were opened or closed. This distinction between central and sensory ataxia has been made by Professor Mendel. The drug did not exert any unfavorable influence over the heart and circulation—which appears opposed to the warning of Dr. Schmey not to use sulfonal in angina pectoris and arterio-sclerosis.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 4, 1889.

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR. GEORGE F. SHRADY read the paper of the evening (see p. 205), entitled

SOME OF THE ABUSES OF ETHERIZATION.

DR. WILLIAM T. BULL said that he could in the main concur with everything that the author of the paper had said, and he approved heartily of his graphic denunciation of the rapid or drenching method of administering ether. Not only was the gentle method to be recommended at the beginning of the administration, but even when the patient was anæsthetized the subsequent development of bad symptoms, as stated by the author, could be prevented by its continuance and by the avoidance of a drenching of the patient with ether. His plan was to allow the patient to breathe a little of the vapor of ether at first, and later to give the anæsthetic in larger quantities. When it was given in this way he had never seen any accidents or bad symptoms, and he regarded ether as not only a safe, but even an agreeable, anæsthetic. It was a bad practice for a hospital surgeon to tell one of his internes to go ahead and give ether, while he himself went off to see patients in another part of the hospital. He agreed with Dr. Shrady, that an inexperienced person should not be allowed to give ether. He had met with four deaths under ether in his hospital practice, and had taken pains to ascertain the particulars of the administration in each instance, and in each of these four cases he found that the patient was in the hands of the junior assistant at the time death took place. Almost the only disagreeable occurrence which was apt to be encountered, when ether was given in the proper manner, was bronchorrhœa, but this was sometimes so annoying that he had been led to substitute chloroform in certain operations about the larynx.

He had not used morphine before the induction of the anæsthesia, but had, in the case of certain plastic operations, administered the drug hypodermically after the patient was thoroughly anæsthetized, and his experience had taught him that this method was one of great value.

He was not prepared to assert positively that the administration of ether to patients suffering from albuminuria was free from danger, yet he was personally inclined to believe that this danger had been exaggerated. The speaker had operated on many cases of urethral stricture, complicated with cystitis and albuminuria, and had never seen any bad effects from the ether administered. This experience had led him to believe that there was no especial danger in giving ether in cases of kidney disease.

DR. CHARLES L. DANA said that he had occasionally been struck by statements made to him by patients suffering from nervous disorders, who referred the commencement of their troubles to the time when they had taken ether. The operations in these cases were of a trivial nature, and not likely to have been the cause of the nervous disturbances noted. He thought it not improbable, therefore, that certain neuroses, as stated by Dr. Shrady, might be originated by the administration of ether, although the possibility of such a cause for the production of disorders of this kind did not seem to have been generally recognized.

DR. JOSEPH D. BRYANT said that he had always thought that one of the leading abuses in the use of ether was that its administration was entrusted to the junior hospital surgeons, for it was certainly a bad practice to entrust such an important duty to an inexperienced person. What sort of an ether cone might be selected was of less importance than the proper employment of the one that was used. The inhalation of ether should begin very gradually, and later it could be pushed more rapidly. A moderate-sized dose of whiskey, given before the administration of ether was begun, was often of good service. There was another abuse that was very common, and consisted in the shaving or scrubbing of the part to be operated upon, by the senior, while the junior was engaged in giving the ether, thereby disturbing the patient, and rendering the induction of anæsthesia more difficult. During the administration of an anæsthetic the patient should not be disturbed in any way, either by being handled or by the talking of those about him. The speaker said that he had been particularly fortunate in not having witnessed any serious accident during the administration of ether since the time when he was serving as interne in the hospital. During his term of service a patient died under ether. The urine contained albumin and casts, and a post-mortem examination showed the existence of nephritis. He had several times seen dangerous symptoms arise, but whenever that happened it was always found that the giver of the ether was looking at the operation instead of attending to the patient. The simplest means of preventing closure of the glottis was to push the lower jaw forward, and this was far preferable to drawing forward the tongue by forceps. He did not wish to be understood, however, as advocating constant pressure against the angles of the jaw, a proceed ure which Dr. Shrady had protested against, and one that was likely to produce a soreness lasting perhaps for several days. It was to be done only occasionally, and when indicated by symptoms of closure of the glottis. As to the use of ether when kidney complications were present, his experience in connection with urethral operations had been of such a nature as to lead him to discard ether in these cases. He now always employed chloroform when he found disease of the kidneys present.

DR. ROBERT F. WEIR said that the general impression that ether was a safe anæsthetic was not entirely correct. He had on a previous occasion gone over the records of operations at the New York Hospital for a long series of years, to determine this very point. He had collected the statistics of some twelve thousand operations performed under ether, and of these there were six deaths attributed to the anæsthetic, or one in every two thousand cases. It had been stated that the proportion of fatal cases in chloroform anæsthesia was one in twenty-five hundred, and from ether one in twenty-five thousand; but deaths from chloroform were much more frequent than this, and, as the result of his investigations would seem to show, the proportion given for ether was also too low. While he believed that ether was far more safe than chloroform, it was nevertheless a fact that the use of any anæsthetic was much more dangerous than was generally supposed, and hence the necessity of constant watchfulness during its administration. He did not believe that ether was in itself especially dangerous in those cases in which a kidney complication existed.

The speaker did not look with favor on Howard's method of opening the glottis, by allowing the patient's head to fall back over the end of the table. He had tried it recently in a case upon which he was operating, but without success. He had also tried it in his own person, and had found that it rather impeded respiration. Several years ago he had placed a patient in this position, during an operation upon the mouth in which there was considerable hemorrhage, in order the more easily to prevent the blood from flowing into the larynx, but the patient stopped breathing almost immediately, and the attempt had to be abandoned.

DR. BEVERLEY ROBINSON had been unable to satisfy himself as to the danger of etherization in cases of kidney disease. He had always watched such cases with considerable interest, but had not yet seen evidence enough to convince him that the ether was a source of danger, though he was not prepared to deny that it might be The same was the case in regard to disease of the heart, although he said he would be loath to give ether or to se:

it given to a patient suffering from serious cardiac trouble. As to the case of pulmonary disease, he had seen a death during anæsthesia occurring in a patient suffering from phthisis, and he believed that it was directly attributable to œdema of the lungs caused by the ether.

Dr. Samuel Sexton said that, judging from the remarks that had been made by Dr. Shrady and by those who had taken part in the discussion, he thought that it was time some reforms were brought about in the matter of administering ether. He had witnessed the administration of this anæsthetic to young children in what seemed to be a most cruel manner. The child would be held by the hair of the head, and during its struggles the head would be brought down forcibly against the table, thumping it in no gentle way. He was always in the habit of instructing his patients to breathe out fully several times at the beginning of the administration of ether, as suggested by the author of the paper, and in this way it was possible to get rid of some of the residual air. After a few forcible expirations the ether was given, and then acted, as he believed, more efficiently and pleasantly. He had recently been interested in the question as to the time required to produce profound anæsthesia in adults. In a few cases, in which the time had been accurately noted, he had found complete anæsthesia produced in from fifteen to twenty-five minutes. The ether in these cases was given carefully, and not by the drenching method. In operations on the ear profound narcosis is requisite, since otherwise the patient will vomit from reflex influences propagated from the ear when the first incision in the drum-membrane is made, thus interfering with the operation. Such an experience would not, of course, occur while the surgeon was operating on any other part of the body.

Dr. James B. Hunter believed that ether was largely eliminated by the kidneys, and when the kidneys were diseased there was danger in its administration. He agreed with Dr. Shrady and Dr. Bryant, that the room in which the person was being anæsthetized should be perfectly quiet, and that the patient should not be disturbed by talking or by preparations for the operation. He thought also that the kind of cone used was a matter of less importance than was the manner of administering the ether. The time required for the induction of anæsthesia was usually from three to five minutes, and he had never seen so long a time as twenty-five minutes so consumed. He regarded Clover's or Ormsby's inhaler as the best apparatus, and it was also much more economical in the amount of ether employed, as from one to two ounces was the average amount required for the induction and maintenance of anæsthesia during an ordinary operation. The patient should take several long inspirations and expirations at first and then breathe deeply, when the ether should be pushed rapidly. One great advantage of Clover's apparatus was that vomiting was the exception after the administration of ether by means of it. He believed with Dr. Shrady that too much care could not be taken in administering ether by the junior assistants in hospitals, that as a rule they were not properly qualified to do so, and that it would be well for the Society to endorse the views of the author of the paper by an authoritative expression of opinion on the subject.

Dr. Weir had noted the time necessary for the induction of complete anæsthesia in thirty or forty cases. When the ether was crowded the time required was between four and five minutes, but by the slower and more pleasant method from eight to ten minutes were consumed.

Dr. V. P. Gibney asked whether the primary object of the administration of morphine, as mentioned by the reader of the paper, was to aid in prolonging the anæsthesia, or to stimulate the heart's action. He had been in the habit for some time of giving the drug on account of its action as a heart stimulant, and had had frequent occasion to observe the good effects of this method.

Dr. Shrady replied that he had both objects in view in giving the drug, though it was primarily as a safe and efficient means of prolonging anæsthesia that he had recommended its use.

Dr. William M. Polk said that he had abandoned the use of undiluted ether, as administered by the ordinary methods, and confined himself pretty much to giving the anæsthetic by Clover's apparatus, which he looked upon as superior in many ways. Ether was a rank poison, and was liable to act badly when least suspected, and no one could tell what the result would be in any given case. Ether was often given without any previous examination of the organs of the body, and this was the explanation of some of the disastrous cases which had been recorded. A careful inquiry of all the organs, which we know are liable to behave badly when the patient is under the influence of ether, should be made. Attention should not be directed to the kidneys alone, but to all the organs of the body. If any disease is found, then the patient should be warned of the danger, though the speaker would not refuse to give ether under such circumstances if necessity called for its administration. He regarded chloroform as a safer anæsthetic in cases of pulmonary disease.

Dr. George L. Peabody did not believe that ether was specially dangerous in an ordinary case of chronic Bright's disease, and thought that the presence of such an affection should not be regarded as a contra-indication to the administration of the anæsthetic. Nor did he believe that the existence of a well-compensated valvular affection of the heart offered any special contra-indication. Ether should not be administered ordinarily in cases of bronchitis, though patients suffering from empyema bore ether well in his experience. It was a matter of great importance to instruct the receiver of the ether as well as the giver. A little judicious talking to a patient about to take an anæsthetic would often be productive of much good. A rapid mode of giving ether, which would seem to be free from many of the objections raised against the drenching method, had been used to some extent in Philadelphia. This consisted in warming the ether, and conveying only the vapor to the inhaler. In reply to an inquiry, the speaker said that he had no facts to present bearing on the question of the danger of giving ether to patients with glycosuria.

Dr. J. West Roosevelt did not think it at all safe to give ether in cases of empyema. He had seen two cases of this sort in which respiration ceased. One case died, and the other recovered after the employment of artificial respiration. In the case that died the ether had been administered with the utmost care.

Dr. Weir had also seen two such cases, and now never permitted ether to be given in a case of marked empyema.

Dr. Polk related a case of a patient operated upon for the closure of an intestinal fistula, who was suffering at the same time with nephritis. The patient died in uræmic convulsions a few hours after the operation had been performed. In this case Clover's apparatus was used, and only about four ounces of ether had been consumed.

Dr. Weir said that he had tested the urine of patients with Bright's disease after the administration of ether, but had found no increase in the quantity of albumin.

Dr. Bull said that Clover's apparatus was ill suited to general surgical use, as it was necessary to instruct every new man how to employ it. It was inconvenient also in operations upon the upper part of the body. Not more than five or ten minutes should be consumed in the etherization of an ordinary patient. From six to eight ounces of ether should be enough to keep a person anæsthetized during an operation of from a half to one hour's duration. He regarded empyema as a much more important contra-indication to the administration of ether than other conditions, such as heart disease. He referred to the question of

MANIA FOLLOWING ETHERIZATION,

and said that it must have been within the experience of all present to have seen nervous disturbances excited and

continuing for quite a time after the administration of ether. He recalled one case in which the patient was delirious for four days after having been etherized, not recognizing anybody during all this period.

Dr. Bryant had seen a similar case occurring in the person of a Cuban, upon whom he had operated. There was no history of insanity in the patient's family. His reason was eventually perfectly restored.

Dr. Polk had met with two such cases. In both instances the patients had always been a little queer, though not in any sense insane. He had attributed the pronounced nervous disturbances in these cases to the shock of the operation, and not to the effects of the ether.

Dr. Hunter had also seen two cases of temporary mental disturbance following etherization.

Dr. Shrady, in closing the discussion, said that he had, perhaps, been misunderstood in respect to the weight of importance attached to the danger of giving ether to patients with Bright's disease, yet he believed that there was more or less danger under such circumstances. In common with other surgeons, however, he had often operated without accident upon patients with Bright's disease in cases of emergency, notably for strangulated hernia, and extravasation of urine, but it was always with some misgiving based upon the warnings of Emmett, Van Santvoord, and others. He did not regard a well-compensated valvular affection of the heart as offering any special contraindication to the administration of ether. He seldom gave ether to children under five years of age, preferring chloroform in such cases. He had used Clover's apparatus with satisfaction in some instances, but preferred the cone in ordinary cases, by reason of the fact that its mode of employment was better understood by most people. A better effect was obtained in mixed narcosis when the morphine was administered before than after anæsthesia was established. He had had no personal experience in the application of Howard's method of raising the glottis in cases of suspended breathing. He was much pleased to hear his views regarding the abused methods of etherization endorsed by the different members, and thought that the recommendation by Dr. Hunter, that the Society should take some action in the matter, especially with reference to the administration of ether by the younger members of the hospital staff, was a good one.

After some discussion the President appointed a committee for that purpose consisting of Drs. Hunter, Weir, and Shrady, who should report at the next meeting.

The Society then adjourned.

Pessimism.—Pessimism can find no better stimulus to effort than the desire to lessen the appalling weight of human woe which, according to its exponents, must ever remain overwhelming, and ever resist every effort for its successful mitigation. It points to no Land of Promise, the prospect of whose milk and honey may inspirit the weary travellers through the wilderness; it sings no pæans over a coming era of freedom, plenty, enlightenment, and peace; it bluntly informs humanity that its lot is evil, that its best efforts will never achieve aught but some trifling mitigation of its sufferings, and that there is hope neither in the future of the race nor beyond the grave. These doctrines are in every respect identical with the teaching of *Gautama*, whose influence in the Eastern World has been so potent. Berlin has answered Benares in the cry that life is evil, that hope is vain, that only in self-renunciation will the cravings of man find solace and rest. When we come to consider pessimism from the impartial point of view of scientific scrutiny, we become impressed with the conviction that it indicates less a normal development of human thought than a moral and intellectual disease—the outcome in all probability of the unhappy surroundings of the individual, or the untoward tendencies of the epoch. If life be stigmatized as worthless, the general sense of humanity will conclude that the speaker has probably made shipwreck of its worth.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LETTSOMIAN LECTURES AT THE MEDICAL SOCIETY OF LONDON—THE METROPOLITAN HOSPITAL AND ITS PROVIDENT SCHEME—ST. JOHN'S HOSPITAL—THE LANDER INSTITUTION.

London, January 29, 1889.

Dr. Gowers' Lettsomian Lectures, at the Medical Society of London, have been devoted to the subject of "Syphilis and the Nervous System." In his first lecture he remarked that, comparing the various syphilitic lesions, not limiting our view to any single organ, we seemed to discern in them two elements—a process of inflammation, and a process of tissue-formation. The latter was seen in almost a pure form in gummata. The inflammatory or congestive element was almost or quite pure in many of the early skin eruptions, in some cases of iritis, and in many other lesions. Generally the two elements were combined and the most common condition was that often termed "hyperplastic inflammation." There seemed to be a tendency for the congestive or inflammatory element to preponderate in the early lesions, and the tissue-formation in the later—though to this the earliest lesions, the primary induration and the enlargement of the nearer glands, were apparent exceptions. It had been suggested that there was no real difference between these two elements, that the tissue formed in syphilitic processes differed but little from that formed in ordinary inflammation, and was combined in various quantity with the signs of inflammation. But the tissue formed presented certain characters not found in the same degree in ordinary inflammatory products, viz., its peculiar aspect (gluey appearance) when of recent formation, and its tendency to undergo certain changes—as to caseate or change to a contracting fibrous tissue. The latter change was of extreme importance in relation to the symptoms produced by which the lesion was manifested.

Syphilitic lesions might be divided into certain classes and we might expect to find these classes represented in the nervous system. First, there were morbid processes with characters that were peculiar, processes due to no other cause. Secondly, there were processes that were not peculiar; they resembled those due to other causes, though they were due to syphilis. Others had not even this peculiarity, but might be described as lesions due to many causes, of which syphilis was one. Speaking generally, the more the congestive or inflammatory element preponderated in a lesion, the less special were its pathological features. These depended chiefly on the element of tissue-formation. Necessarily also, as the latter needed time, the more acute a syphilitic inflammation was the less were its features distinctive. This was an important consideration.

Among the lesions of which syphilis was the only cause there were first the syphilitic growths (gummata) which grew commonly from the surface of the pia mater, and both compressed and invaded the substance of the brain or spinal cord. They were rare within the substance of the brain, and rare also, though sometimes symmetrical, on the cranial nerves. Secondly, there were the growths in the walls of the arteries which constituted one of the most important of the specific lesions. The remarkable correspondence in seat with atheroma must be noted. Certain of the pathological consequences of this arterial disease must not be passed over. The first was the necrotic softening that followed occlusion of the diseased artery, or more often that of a branch coming off from the diseased spot; it was by this softening that the disease most frequently caused symptoms. Occlusion, however, did not always lead to softening; induration might occur, especially in the cortex, and more often in children than

in adults. It was, no doubt, due to the arterial anastomoses being sufficient to prevent actual necrosis, though insufficient to maintain the integrity of the tissue. A second effect was the production of aneurism of the larger arteries, those that were the special seats of the disease. We knew two other causes of such intracranial aneurisms: one (very rare) was traumatic arteritis, the other was embolism which was probably the cause of three-quarters of these aneurisms before the degenerative period of life. In the remainder, in which there was no history of injury and no evidence of embolism, there was a history of syphilis in so many cases as to justify an opinion that most of them were due to it. A third and very rare effect of syphilitic disease was hæmorrhage within the substance of the brain. Inflammation that was specific in its pathological features was chiefly meningeal. Much new tissue was produced, and this might undergo either the caseous or the fibroid change. Either of the two membranes might be inflamed. In the dura mater the inflammation was usually diffuse, and the tissue formed underwent chiefly the fibroid change; in the pia mater the inflammation was usually local and the new tissue abundant. Inflammation of the substance of the brain or cord, that could be regarded as pathologically specific, was very rare. Very little was definitely known of inflammation of the cranial nerves that was pathologically specific. Dr. Gowers remarked that in speaking of specific pathological characters he had alluded only to those that could be recognized by the naked eye. He did not think that at present any confidence could be placed on histological characters only; even the structure of a gumma was not distinctive.

Were there any lesions of the nervous system that could be said to belong to the second class?—lesions that presented no pathological peculiarity, lesions that were due to other causes besides syphilis, and yet, when syphilitic in origin, had peculiarities of distribution not present when they were due to other causes. A few possibly might be of this character. One was a form of disseminated myelitis in which defined islets of inflammation occupied the white substance of the cord, chiefly near the surface, and were, perhaps, sometimes met with in the brain. This form had been described, as related to syphilis, by Julliard and Pierret, and the lecturer said he had himself met with one case. The facts at present did not prove specificity apart from distribution, and the same might be said of a form of multiple inflammation of the spinal roots, regarded as specific by Kahler, and of certain forms of sclerosis of the cortex of the brain (without arterial disease) met with by Barlow in infantile syphilis. It was not likely that this completed the series of obviously specific lesions. Many other morbid processes might yet be added when our knowledge of them was rendered adequate by a sufficient number of observations.

The chief morbid lesions of the remaining class—that in which the lesions were due to many causes of which syphilis was only one—were certain acute and subacute inflammations, and certain forms of chronic inflammation or focal sclerosis of the nerve-centres. In the same category must also be placed the important class of primary nerve-degenerations. The question of evidence was of the greater importance in regard to this class because we had to proceed to some extent without the aid of pathological observation, opportunities for the latter came but seldom, and it was doubtful whether, when they did come, they afforded any real help. In the case of these apparently simple lesions, only two kinds of evidence seemed at present within our reach. The first was such sequence as proved causation; the second was the evidence of therapeutics. Regarding the evidence of sequence the first important consideration was that isolated instances of sequence were no scientific proof of causation. Sequence could only prove causation by the strength of numbers. Dr. Gowers then discussed the question of the prevalence of syphilis, and said the first question was to ascertain the average frequency of past or present syphilis in males over twenty-five years of age. After giving some statistics from various sources and discussing them, he said that, whatever the ascertained proportion of syphilis it would assuredly fall short of the truth. With regard to the evidence from therapeutics, he said that the method was applicable chiefly to chronic lesions in which the influence of treatment could be clear and decided. Acute lesions, if slight, had too great tendency to subside; and, if severe, had effects of prolonged duration. Among the lesions to which these methods of proof applied there were, firstly, two important acute inflammations, those of the membranes of the brain and of the substance of the cord. Were these ever due to syphilis? That syphilis caused chronic meningitis was one of the surest facts in medicine, but it was still uncertain whether it also caused acute meningitis. The possible relation of acute myelitis to syphilis was one on which evidence was needed. The term included diseases widely different. We could distinguish acute transverse myelitis, subacute disseminated myelitis, and acute poliomyelitis. Not one of these was exclusively related to syphilis. Referring to the form of insular myelitis he had mentioned, Dr. Gowers said that, if syphilitic, it did not seem distinctly amenable to treatment, for in the cases hitherto observed the patients had died. With regard to acute transverse myelitis, he had seen several cases in which the disease followed syphilis—more that mere coincidence would explain. He had met with no cases of acute poliomyelitis suggesting a syphilitic origin. Acute ascending paralysis had been supposed to be a result of syphilis, partly on the ground of sequence, partly on that of recovery under the influence of mercury. The proportion of published cases in syphilitic subjects was certainly large and justified careful investigation. The evidence seemed to be against any relation to syphilis of true insular sclerosis, and only future observations could determine the question as regarded other extremely rare forms of diffuse sclerosis.

Until lately it was believed that the influence of syphilis was limited to the production of such lesions as those he had considered. But modern observations had shown that syphilis might cause degenerations of the nerve-centres. This relation was first asserted in the case of locomotor ataxy, but we were beginning to discern that there were other diseases that stood in a similar, although unequal relation to the disease. Dr. Gowers referred to the degenerative ocular palsies, simple atrophy of the optic nerve, ophthalmoplegia, general paralysis of the insane, and chronic muscular atrophy due to degeneration of the motor cells with or without the signs of lateral sclerosis. This was perhaps an occasional consequence of syphilis, and great care was necessary to avoid mistaking for it the atrophy that resulted from syphilitic pachymeningitis. The other common forms of degenerative diseases of the spinal cord were associated with syphilis in a proportion so small as to raise a doubt as to whether there was any causal relation between the two. Nevertheless, they occasionally followed syphilis when no other cause could be traced; this was especially true of the primary lateral sclerosis that probably often underlay spastic paralysis.

In his second lecture, after remarking that to the long list of maladies, the certain or supposed consequences of syphilis, should be added some of the functional diseases of the nervous system, Dr. Gowers went on to discuss the subjects of symptoms and diagnosis. The lesions of the nervous system were wholly beyond the range of observation, and we could not dispense with the careful consideration of each step we took. The essential steps were: 1. What was the seat of the lesion as indicated by the symptoms, and what was its nature as indicated by their course? 2. Was the process thus indicated one of those that might be specific? 3. Had the patient had syphilis? 4. Could any other cause of such a morbid process be traced? 5. We had to see whether the result of treatment confirmed our conclusion. The lecturer

then discussed these points in detail and then proceeded to the consideration of the symptoms of some particular syphilitic lesions. Speaking of syphilitic growths, he said a gumma caused symptoms like any other intracranial tumor of rapid growth, and focal symptoms due to the local influence of the growth. Their special features were never more than suggestive. They depended on the course, which was acute or subacute, and on the fact that gummata were more frequent in certain parts. Their seat was generally superficial, in the cortex or at the base, sometimes within the pons, seldom in the cerebellum, occasionally in the thalamic region, growing in from the side of the crus. Hence symptoms of cortical irritation were more frequent than in other tumors; convulsions were common and gave important information, from their local distribution or commencement or from the aura that equally indicated the spot at which the discharge began. The indication afforded by the course of the symptoms was chiefly negative. A very chronic growth was not likely to be syphilitic. We might often gain instruction from the optic neuritis so often present. Syphiloma caused an acute form of optic neuritis. A rapid growth never caused a chronic form of neuritis, although now and then a slow growth might cause an acute form. Hence while acuteness of the neuritis was of little diagnostic value, chronicity was distinctly opposed to the diagnosis of a syphilitic growth. The effect of treatment was of considerable diagnostic value. It usually caused a prompt diminution in the symptoms, but, to be of significance, this effect should be considerable and involve both the local and general symptoms.

The discussion about the Metropolitan Hospital shows no signs of abating. This hospital was originally styled the "Metropolitan Free Hospital," and was, I believe, free to all comers without letters of recommendation. When the new building was opened, a year or two ago, this was altered, and the out-patient department was made "provident" in character, patients being required to subscribe a small sum regularly, per week. The word "free" was dropped from the name of the hospital. The immediate result was doubtless an augmentation of the finances of the hospital and some diminution of the crowds of out-patients. Another result, however, has been to injure the practices of the medical men in the neighborhood. At least, the latter allege that this has been the effect of the change. The storm which has been raised is one which will not, I think, be easily appeased, and in any case it is difficult to imagine how it can be justifiable to convert a free hospital, erected solely by public subscriptions and donations, into an institution of such a different character and limited local sphere of operations.

The action brought by the secretary of St. John's Hospital for Skin Diseases against a comic paper called *Ally Sloper* has terminated in a verdict for the plaintiff, with three hundred pounds damages.

The evidence showed considerable irregularities in the financial arrangements of the hospital, but the plaintiff was able to prove that he had committed no dishonest action as imputed to him by the defendants.

Possibly some of your readers may have heard of the Lander Institution in London for the carrying out of the "movement cure." This was at one time conducted on a scientific basis, and many medical men of position sent patients to it for treatment. Presumably it did not pay, for the institution has recently changed hands and has been annexed to a galvanic institution which is notorious as a hotbed of quackery. The medical men who patronized the Lander Institution are now horrified to find their names made use of by the quackish institution in question. We have probably not yet heard the end of the matter.

THE DAILY PAPERS state that another man has successfully extirpated a human breast and that the patient will probably recover.

ELECTROLYSIS IN STRICTURE.

(OPEN LETTER TO DR. NEWMAN.)

THROUGH THE EDITOR OF THE MEDICAL RECORD TO

DR. ROBERT NEWMAN.

SIR: In the recent discussion as to the merits of electrolysis in the radical cure of urethral stricture, it is possible that the failures of Professor Keyes may be attributed to faulty methods, while your own failure, in the case reported by Professor Keyes, is only conclusive as a single case.

It seems to us to be a comparatively easy matter to settle the disputed point (as you are aware, one of the greatest interest to the whole surgical world); *i.e.*, whether electrolysis is of any value whatsoever in the treatment of organic urethral stricture.

We would, therefore, be pleased to provide ten patients, subjects of organic stricture, as determined by a committee of competent surgeons, with a request that you will choose five from this number, and demonstrate the advantages of your method upon them. In the meantime we shall be glad to treat the remaining five by dilating urethrotomy. After treatment, we would request that there be no instrumental interference, of any kind, for a period of at least one month, when they shall be re-examined by the original examiners, and the condition of their urethras reported on, said report to be sent to every medical journal in the United States, and, as far as possible, abroad, with a request for publication.

Feeling you will gladly accept this proposition to vindicate the merits of your methods, we remain,

Sincerely yours,

GEORGE E. BREWER, M.D.,
WILLIAM K. OTIS, M.D.

VANDERBILT CLINIC, GENITO-URINARY DIVISION,
NEW YORK, February 6, 1889.

THE ASSOCIATION OF ACTING ASSISTANT SURGEONS, UNITED STATES ARMY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The Association of Acting Assistant Surgeons, United States Army, has met with the most cordial interest and support from many past and present acting assistant surgeons. We have representatives in most of the States and Territories. We find considerable interest manifested by the medical profession, and by relatives of deceased officers. The original intention was to obtain a complete list of all who have served as acting assistant surgeons, but this has been found impracticable, and our future work will be directed to accomplish the following objects: First to make careful and well-managed efforts to obtain a better position and to present a properly prepared "petition, signed by the acting assistant surgeons and endorsed by assistant surgeons, surgeons, and others who may favor the same, to the Military Committee of the next Congress, praying that acting assistant surgeons of the army (now serving), many of whom have served long and faithfully, performing all the professional duties of commissioned surgeons, and many of whom are past the age permitting them to apply for examination for commissions as first lieutenants in the medical corps, be commissioned assistant surgeons with the rank of second lieutenant of cavalry, not to be in the line for promotion, the pay (that of second lieutenant) not to be increased, and to be allowed forage for one horse; that at the expiration of the regular full term of service, or on account of disability, they be placed on the retired list of the army." This would be an act of tardy justice to men who have faithfully served and performed the duties of men whose pay is that of first lieutenants, captains, and majors. Every man in the employ of the United States Government should be entitled to justice, and, in case of trouble with his superior officer, to a fair trial before being deprived of his position and means of subsistence.

As it is at present, an acting assistant surgeon may be dismissed at any time, without the right to appeal for a trial or to demand that ordinary justice be afforded him. The objects aimed at in this petition are honorable and just, and would in no degree conflict with discipline or have other than a wholesome effect upon the medical corps in general.

The association will, as soon as sufficient funds can be obtained, publish a little book giving the history of the corps and the personal and medical histories of the members of the association. It will contain histories of battles in which acting assistant surgeons have taken part, and of those who lost their lives in the service of their country. It will also endeavor to collect funds to purchase and place in the military chapel at Fort Leavenworth, Kan., a suitable tablet in memory of the acting assistant surgeons of the United States Army who have fallen in the line of duty. Many interesting and valuable memoirs of acting assistant surgeons have already been received, not only from those who are members of the association, but from friends of deceased surgeons. All past and present acting assistant surgeons should join the association as soon as possible to aid in the worthy objects we have in view. It is hoped that a meeting may be held in Newport during the meeting of the American Medical Association.

At this meeting, although few active assistant surgeons can be present, the Association will discuss the best methods to aid in improving the status of those who are now serving, and do everything in its power for their welfare. The badge of the Association is the Geneva Red Cross. The enrolment fee is $1, and the yearly dues are $1. Application blanks will be forwarded by the Recorder,

W. Thornton Parker, M.D.

322 Benefit Street, Providence, R. I.

THE IMPROVED WINGHURST INFLUENCE MACHINE.

To the Editor of The Medical Record.

Sir: Last spring Professor Winghurst exhibited in London an entirely new form of influence machine, which was unanimously admitted by experts to be in every respect superior to any previous style of static machine. It was natural that scientists, and especially physicians employing franklinic electricity, should be attracted by the glowing accounts given of Professor Winghurst's invention, but I believe the credit of having manufactured the first static machine on Winghurst's principles is due to Mr. Thomas Harris, of this city, an electrician of remarkable skill and exceptional ingenuity. The original machines, while superior to either the Toepler or Holtz, still lacked the necessary features to insure their being freely excited under all atmospheric conditions, and it was to this point in particular that Mr. Harris turned his attention, with the result that the machine in my office never fails to yield an ample quantity of electricity at all times without any warming of discs, the use of chloride of calcium, or other accessories, without which no owner of a Holtz or Toepler can be sure of his machine doing efficient work.

The improved Winghurst machine, as it stands to-day, differs in some respects from the first machine built by Mr. Harris for my friend Dr. Younghusband (to whom the credit is undoubtedly due of being the first to appreciate the superiority of the Winghurst) as it has been found that by a different arrangement of the sectors on the glass disks a much longer spark is obtained, while the certainty of the machine readily becoming excited is by no means diminished.

So far the machines have been made with six revolving glass disks, each pair revolving in opposite directions, the size of the disks being twenty-four, thirty, and thirty-three inches respectively. The machine in my office is composed of thirty-three-inch disks, and readily yields a spark a foot long between the discharging rods of the prime conductors, while for static insulation, or, as some prefer to call it, general franklinization, a speed of fifty revolutions a minute is ample for the average patient. For the indirect or direct spark I increase the speed to one hundred. Aside from the annoyance of caring for the old style of machines, the uncertainty of being able to treat patients at all seasons of the year caused the use of static electricity to be confined to comparatively few, although I hardly think any will deny its many advantages over faradism or galvanism. Now that a perfectly reliable machine has been produced it is safe to predict that in a very short time franklinism will regain that place in electro-therapeutics which but for the inconveniences enumerated it would never have lost. In my estimation, and I have had more than ample facilities for proving my assertion, I regard the Winghurst machine with the Harris improvements as immeasurably superior to all other forms of static machines, as I do the use of the Edison incandescent light wire for galvanic work to the filthy and irritating bichromate battery.

Respectfully yours,

H. Montague, M.D.

271 Woodward Avenue, Detroit, Mich.,
January 25, 1889.

THE MICROSCOPE AND THE NEW YORK PATHOLOGICAL SOCIETY.

By JOHN C. PETERS, M.D.,

New York.

A short time ago I received a note from the President containing these words:

"Was Dr. Alonzo Clark the first to bring the microscope into use in pathology in New York? A story of the early dawn of microscopic insight into lesions, in New York, would read like a novel to most of us. Suppose you sleep over this, and see what comes into your mind in the morning. Very sincerely yours,

"W. P. Northup.

"To J. C. Peters, M.D."

It must be borne in mind that Queckett's book on the use of the microscope was not published until 1848; Robin's in 1849, when Oliver Wendell Holmes was singing about thus:

"I was sitting with my microscope, upon my parlor rug,
With a very heavy quarto and a very lively bug,
I lost my focus—dropped my book—the bug, which was a flea,
At once exploded, and commenced experiments on me."

Virchow's book did not appear until 1854, nor Beale's "Application of the Microscope to Clinical Medicine" until 1859.

At the thirteenth meeting of the Society, held at Dr. Willard Parker's, at the corner of Broadway and Eighth Streets, on December 24, 1844, the following was recorded:

"So many specimens were presented, and the wonders of the microscope were of such absorbing interest, and the supper was so good, that the Secretary [Dr. William C. Roberts] found himself quite unable to record all the proceedings.

"*Present:* Drs. Parker, Markoe, Sabine, Sayre, Crane, Middleton Goldsmith, Roberts, Watts, Macnevin, W. W. Jones, Isaac E. Taylor, John C. Peters, Cock, Moses, Tomes, Metcalfe, and Alonzo Clark—in all, 17."

On January 22, 1845, Dr. Alonzo Clark demonstrated the difference between atheroma and tubercle under the microscope, and reported about Dr. Taylor's specimen.

On April 23, 1845, Drs. Markoe, Sabine, Taylor, and Roberts were made a committee for the examination of morbid specimens, and Dr. Taylor was directed to keep his eyes open for meconic membranes.

May 14, 1845. A diseased testis was referred to Dr. Clark for microscopical examination. May 28th, $135

was subscribed for the establishment of a museum, the purchase of a microscope, and a dissecting case. [The microscope was not purchased until 1851.]

December 10, 1845. Dr. Clark gave a microscopical description of so-called false membranes from the bowels; he said they were merely amorphous material with mucous globules, and not at all organized; he also said the microscope could now distinguish the difference between lymph and tubercle.

December 24, 1845. Rice-like bodies from a ganglion were decided by two incipient microscopists to be hydatids, but by Dr. Clark to be rolled-up epithelium.

February 25, 1846. Dr. Clark demonstrated microscopically the difference between tubercle and a fibrinous deposit.

The microscope excited so much interest that on July 8th, when the time for the usual summer recess came round, it was resolved to continue the meetings until further notice. A microscopical account of a polypus of the uterus escaped the Secretary's ears while he was looking into the microscope.

October 27, 1846. Dr. Van Buren showed trichina spiralis under the microscope. A secretary *pro tem.* recorded cases of *croup de soleil, scrofulous carcinoma, and ensilage cartilage!!* and there were only thirteen cents in the treasury.

April 24, 1847. Dr. Charles E. Isaacs gave the microscopical appearances in a case of seminal emissions; the urine was full of filaments of mucus, nucleated cells, and granules; urinary salts crystallized on the glass slides, and many spermatozoa were found. On standing, the urine exhibited many *vibriones*, or small attenuated particles, like grains of sand, all moving very rapidly and "revolving on themselves," very much like bacteria.

May 27, 1847. Dr. Van Buren, in a case of supposed cancer of the leg, reported the presence of caudate corpuscles [connective-tissue cells?] as among the most characteristic microscopical appearances of encephaloid cancer. Dr. Clark denied this, and said that cancer could not yet be diagnosed by the microscope alone. He also reported the examination of a supposed fatty tumor of the thyroid gland; it was not fatty, but he could not decide exactly what it was; still it was made up of small vesicles separated by tough filaments of cellular tissue and blood-vessels.

June 9, 1847. Dr. Clark repeated that the so-called caudate corpuscles could not be depended upon as microscopically characteristic of cancer.

June 23, 1847. Dr. Isaacs reported a steatomatous tumor as composed of one-third cholesterine and two-thirds of epithelial cells. Another tumor was made up of amorphous matter, granules of carbonate of lime, and something like pus-cells. Dr. Metcalfe moved that a suitable microscope be procured for the Society, and he and Dr. Isaacs were directed to buy one, but this was not done until 1851; in the meantime many of the members got microscopes for themselves.

July 14, 1847. Dr. Clark pointed out the difference between fatty and lardaceous livers. Malignant tumors were presented by the score, but the gross appearances were generally relied upon in the diagnosis of them. Drs. Markoe, Sabine, Metcalfe, Van Buren, Isaacs, Clark, Sayre, and others distinguished themselves by their accurate knowledge of all the diagnostic signs of malignant disease. Drs. Markoe and Van Buren laid some stress upon the lobster-like and halibut-flesh-like look of encephaloid disease when macerated. These energetic men often presented three, five, seven, or more specimens at one meeting.

December 22, 1847. Dr. Clark examined a supposed encephaloid tumor from the rectus femoris muscle, removed by Dr. Van Buren; he could make nothing out of it, except it was not medullary.

December 29, 1847. Dr. Edward Hall presented a congenital atrophied kidney. Dr. Clark had never seen any structure microscopically like it; it was formed of a unique mass of thickened nucleated cells, very uniform in size and appearance, which acetic acid did not break up into granules, but flattened out into distinct cells, the size of pus-cells. Drs. Clark and Isaacs had now become the most prominent microscopists in the Society, according to Dr. Sayre. Dr. Isaacs had been demonstrator and professor of anatomy, and the assistant of Drs. Van Buren and Batchelder. He prepared specimens with the greatest care for several or more of the members, and posted himself well up in the literature of all interesting subjects referred to him. The Secretary, Dr. William C. Roberts, was also untiring in his efforts to post up the Society on every disease and moot point in pathology which came before it, especially diphtheria.

January 26, 1848. Dr. Metcalfe reported microscopically on fibrinous and other deposits in the spleen. This was a gala evening, and Dr. Van Buren described the minute appearances of a tumor from an aponeurosis near the ankle; it was composed of a little fat and more white, solid fibrous tissue, traversed with blood-vessels, but supposed not to be malignant. Dr. Clark dwelt lovingly on a case of melanosis of the liver, which differed from anything he had ever seen. It was granulated, and every granule had another dark granule of its own; millions of microscopic particles or granules made up the substance of the tumor. The fluid from a cyst in the breast was examined by Dr. Isaacs for Dr. James R. Wood; nine-tenths of it coagulated, and most of it was made up of blood-corpuscles. A tumor, seemingly malignant by the microscope and the eye, was reported as the first which had been removed with the aid of chloroform. The Society had now been meeting for several years at the College of Physicians and Surgeons. Drs. Roberts and Sayre were the Committee on Refreshments, and furnished much ale in a big tin-pail, with few tumblers and still fewer towels, while crackers and cheese in brown paper bags, came from the corner grocery. These viands were partaken of at ten o'clock, and then the Society continued its sessions till midnight. For the first eighteen months Drs. Sabine, Markoe, Moses, Sayre, J. C. Peters, Goldsmith, Parker, and Watts were the most active members. In 1846 and 1847 Drs. Van Buren, Alonzo Clark, Metcalfe, Sabine, Markoe, and J. R. Wood came to the front. They seemed to divide the meetings among themselves; every fourth or fifth meeting Dr. Clark would come with from four to ten carefully prepared and well-studied-out specimens, which the others would discuss and criticise. Then we would have a Markoe night, with a nearly equally full programme, followed by Sabine, Van Buren, Swett, Metcalfe, Sayre, Parker, and others, in due succession.

February 9, 1848. Dr. Robert Watts gave a microscopical study of a tumor from the back of an infant; one-half was made up of capillary vessels, set in a gelatinous, colloid (myxomatous?), amorphous mass, with well-formed nucleated cells lying loose in it, but nothing like fibres were to be discovered. This was thought to be more like fungus hæmatodes than encephaloid disease, and Dr. Clark had no doubt that anyone learned in pathology would think so too; but Dr. Gilman doubted whether malignant disease had ever been found in a fœtus. Dr. Sayre was sure it had, as he had presented more than one specimen. Dr. Metcalfe exhibited a heart from a syphilitic and drinking man, and it was decided that valvular disease never arose from syphilis. The man reformed, and, sad to say, became the victim of profusely bleeding piles. The microscope was appealed to to decide the difference between typhus and typhoid petechiæ and spots. Drs. Metcalfe and Isaacs examined the lymph of dysentery; but got no satisfaction from the microscope in a case of cancer of the brain. Drs. Van Buren and Isaacs collected all the known cases of colloid cancer of the knee-joint, in a paper most elaborately drawn up. The dues, one dollar a year, were increased fifty cents more, to pay for postage stamps.

February 28, 1849. Dr. Parker presented a cystic tumor of the breast, which Dr. Clark considered safest to

regard as cancerous, although he repeated that the time had not yet come when our microscopical knowledge enabled us to decide positively and readily between simple, hard, fibrinous, and cancerous tumors.

Drs. Swett, Watts, and Roberts resembled each other very closely, and might have passed for triplets; even their gold spectacles were much alike. Dr. Isaacs was one of the most gentle of men; his most emphatic expression was apt to be: "Pooh, de diddle de dee." He died during the presidency of Dr. Alfred C. Post, and is known to all the older members of the Society by the beautiful tribute which was paid to his memory by Drs. William H. Van Buren and George F. Shrady.

Next to him and Dr. Alonzo Clark, Drs. Van Arsdale and John C. Dalton were the earliest workers with the microscope; so writes Dr. Gouley.

Dr. Markoe writes: "Dr. Clark was the first and for sometime the only member of the Pathological Society who accompanied the cases he presented with a full account of microscopical appearances."

Many of the beginners seemed to delight in discovering what was called "nucleated and caudate cells," the latter were some times spindle cells. The so-called fibro-nucleated tumors were great favorites as they were held to be non-malignant, but recurrent fibroids were great puzzles.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 10 *to February* 16, 1889.

THE Medical Director will proceed to Fort Buford, Dak., on public business connected with the Medical Department, and, upon completion of duty, will rejoin his station. Par. 8, S. O. 14, Headquarters Department of Dakota, St. Paul, Minn., February 5, 1889.

LORING, LEONARD Y., Major and Surgeon. By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability granted in S. O. No. 6, January 18, 1889, Department of Arizona, is extended six months on account of disability. Par. 23, S. O. No. 35, A. G. O., Washington, February 11, 1889.

AINSWORTH, FRED. C., Captain and Surgeon. By direction of the Secretary of War, to proceed to New York City and Brooklyn, N. Y., on public business. Par. 15, S. O. 38, A. G. O., Washington, February 14, 1889.

MEARNS, EDGAR A., Captain and Assistant Surgeon. Relieved from temporary duty at Fort Pembina, Dak., and to rejoin his station, Fort Snelling, Minn., without delay. Par. 4, S. O. 14, Headquarters Department of Dakota, St. Paul, Minn., February 5, 1889.

Official List of Changes in the Meaical Corps of the United States Navy for the week ending February 16, 1889.

BERTOLETTE, D. N., Surgeon. Detached from the Thetis and to wait orders.

HENNEBERGE, L. G., Passed Assistant Surgeon. Detached from the Minnesota and ordered to the Thetis.

MARMION, R. A., Surgeon. Detached from the Juniata and to wait orders.

OGDEN, F. N., Assistant Surgeon. Detached from the Juniata and to wait orders.

STOKES, CHARLES F., Assistant Surgeon. Ordered to the Minnesota.

WILSON, GEORGE B., Assistant Surgeon. Ordered to the Navy Yard, Mare Island, Cal.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 17, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	7	2
Scarlet fever	347	41
Cerebro-spinal meningitis	1	0
Measles	284	22
Diphtheria	205	55
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

CUTANEOUS SWELLINGS AND MENSTRUATION.—A recent number of Volkmann's *Sammlung Klinischer Vorträge* contains an article by Professor Ernst Börner, of Graz, on the cutaneous swellings sometimes observed in women accompanying menstruation and the menopause. The author remarks in connection with these two processes he has observed distinct, transient, local swellings of the skin, and especially of the face. But without any neuralgic accompaniment, at these times cutaneous swellings sometimes are noticed strikingly like urticaria; they may also sometimes be easily mistaken for erysipelas. Itching is generally absent, and the swelling is sometimes confined to the face, and sometimes it is diffused over the whole body. He notes two distinct forms of this affection, one characterized by increased local warmth and hyperæmia. This form is caused by temporary paralysis of the vasomotor nerves or by reflex excitation of the dilators, with increased influx of blood. The conditions under which transudation takes place through the capillary walls are suddenly changed thereby, transudation in the neighborhood is increased, and distinct swelling of the part implicated takes place. This form is met with principally in poor-blooded women, but sometimes also in those who are healthy. The second form shows no redress or increased heart. The condition in these cases is dependent on increased blood-pressure of one of the large blood-vessels, that disappears before compensatory local hyperæmia can be set up. Before this compensatory hyperæmia has time to take place, the increased pressure communicated to the capillaries has already caused increased transudation in the surrounding tissues. In this class of cases the affected parts often feel colder than the neighboring healthy parts. These cutaneous swellings disappear of themselves at the close of the period. The fact that the whole body may be implicated renders it clear that the cutaneous vessels generally have a certain relationship to the vascular system of the genital tract.—*The Medical Press.*

CARCINOMA AND ATROPHY OF THE STOMACH.—At a recent meeting of the Berlin Medical Society, Dr. Rosenheim, in a paper on the subject of Cancer of the Stomach, said that in fourteen out of sixteen cases of this disease free hydrochloric acid was constantly absent from the gastric secretion. In one case, however, there was an excessive amount. This was a case which had for years shown symptoms of gastric ulcer. Seven months before death there was an increase of pain and vomiting, and a tumor could be felt in the pyloric region. It was found to be an example of "cancer atrophicans," and an explanation of the presence of a large amount of hydrochloric acid was offered in the fact that the mucous membrane generally was not involved. For, as a rule, there is associated with carcinoma a marked condition of atrophy of the gastric mucosa, and it is to this that the deficiency in acid has been ascribed by Ewald and others.—*The Lancet.*

ACUTE PANCREATITIS.

A CONSIDERATION OF PANCREATIC HEMORRHAGE, HEMORRHAGIC, SUPPURATIVE, AND GANGRENOUS PANCREATITIS, AND OF DISSEMINATED FAT-NECROSIS.*

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Continued from page 204.)

PART II.

THE peritoneum usually shows no alterations, although evidence of recent peritonitis may, at times, be found.

The microscopical changes to be found in the diseased pancreas have been sufficiently detailed in the reports of Cases XXVIII. and XXXIII. They consist essentially in the evidence of an extensive hemorrhagic infiltration limited more particularly to the interlobular tissue. Also in the presence of cellular and fibrino-cellular formations in the same tissue. Smaller accumulations of round cells and hemorrhages may be found within the lobules, and the ducts may be filled with indifferent cells. The appearances characteristic of a coagulation-necrosis, also thrombosis of the smaller veins, are to be found in many lobules as early as the third day, as are all the other changes above described. The spongy condition of the hemorrhagic region and the numbers of associated bacteria are indicative of putrefactive changes. Whether these are of ante- or post-mortem origin, the evidence at hand does not decide. Finally, the discovery by Osler and Hughes[59] may be mentioned, where an increased number of leucocytes was found in the semilunar ganglia, and an indistinctness and cloudiness of the ganglion-cells.

In summing up the clinical and anatomical characteristics of these cases we have the following brief description of an affection which wholly justifies the term acute hemorrhagic pancreatitis.

It is a disease which may take place without any well-defined cause, but is most likely to occur in persons who have had previous attacks of gastric or gastro-duodenal dyspepsia.

It begins with intense pain, especially in the upper abdomen, soon followed by vomiting, which is likely to be more or less obstinate, and not infrequently by slight epigastric swelling and tenderness, with obstinate constipation.

A normal or subnormal temperature may be present, and symptoms of collapse precede by a few hours death, which is most likely to occur between the second and fourth days.

The gross lesions are due to hemorrhage in and about the pancreas, and the microscope shows cellular and fibrino-cellular exudations in its interstitial tissue, and necrosis of its lobules.

SUPPURATIVE PANCREATITIS.—In order to more fully appreciate the relation which hemorrhagic pancreatitis may bear to pancreatic inflammation and hemorrhage, it becomes necessary to consider the evidence in favor of other varieties of acute pancreatitis. Although the authorities of the present day make but little mention of a suppurative inflammation, Lieutaud,[60] in the last century, alludes to cases of pancreatic abscess reported by Bartholinus, Tulpius, Aubert, and Patin.

To these may be added those of Riolanus, Bonz, and Gautier, referred to by Ancelet.[60] Clässen[61] states that Blancard, in 1688, described the occurrence of small, purulent points on the surface of the pancreas of a child who died of small-pox. Also that Tonnellé found a suppurating pancreas in two cases of puerperal fever. But the cases thus referred to are almost invariably of but little value for purposes of comparison. Döring,[62] for instance, found the enlarged and indurated pancreas connected with an abscess in the mesentery of the transverse colon, which held some four ounces of offensive yellow pus, apparently proceeding from the pancreas. But the evidence is wanting to show that the pancreas was the source of the disease.

Portal[63] saw the pancreas soaked in pus in the body of a man who died after a violent attack (of gout ?). Again,[64] he found the contents of the abscess often enclosed, as in a pocket, in a membranous sac formed by the cellular tissue which covers the pancreas. He declares that he has seen more than a quart (*deux livres*) thus enclosed. Here, again, the question may be raised as to the nature of the abscess and its relation to the pancreas. His mention[65] of the man who died after extirpation of the testicle and ligature of the spermatic cord, is worthy of note. A large quantity of pus was found in the cord, and a considerable abscess around the pancreas.

It is supplemented by the case reported by Moore,[66] of a young man who was seized with a sudden abdominal pain, which in the course of twenty-four hours became worse, and fixed in the right iliac fossa. There was vomiting, constipation, and chills. For several days the patient was not confined to his bed, but he died on the nineteenth day. The diagnosis was typhlitis. The perforated vermiform appendix led into an abscess which had penetrated the iliac muscle and communicated with the cæcum.

There were one large and several small abscesses in the pancreas. The two main veins were filled with thrombi; there was a portal thrombosis continued to the liver, and a parietal thrombosis of the vena cava.

There were numerous small abscesses in the brain.

The case reported by Percival,[67] as of pancreatic abscess, must be regarded as of somewhat doubtful nature. A man of middle age was sick for three months with jaundice, bilious vomit, and a hard epigastric tumor.

Blood, and finally, fetid pus were discharged from the bowels. Eventually anasarca occurred. The epigastric tumor proved to be the greatly enlarged pancreas, which was scirrhous, and contained a considerable abscess.

The common duct was impervious from the pancreatic pressure, and the liver was "much diseased."

Andral[68] found two small abscesses in the middle of the pancreas.

In order to determine the relative frequency of suppurative pancreatitis, the conditions of its occurrence, its symptomatology and results, the cases in the table on pp. 228 and 229 have been collected.

* The Middleton Goldsmith Lecture for 1889, delivered before the New York Pathological Society, February 16, 1889.

Seventeen Cases of Hemorrhagic Pancreatitis.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
XVII.....	Löschner: Weitenweber's Beitr. z. Med., 1842. Schmidt's Jahrb., 1843, xxxix. 31.	M.	26	Strong. Drinks and smokes. Five years ago, from excesses, attacks of belching, nausea, cardialgia, colic, diarrhœa, burning sensation in upper abdomen.	For 16 days colicky attacks in upper abdomen, becoming more frequent. In past 5 days paroxysms have become more intense; nausea, vomiting, constipation, fever, anxiety, now collapsed. Burning, stabbing, griping pain from duodenum to spleen, toward navel, back, and right shoulder, most severe along curvature of stomach. No stool for several days. Upper abdomen hot, swollen, sensitive. Death in 8 hours.	Pancreas doubled in size, firm, violet. Lobules much enlarged, dark, injected, interstitial tissue, infiltrated with blood. Here and there in the blood, between the lobules, a finely granular, yellow exudation. Connective tissue around the pancreas swollen, friable, bluish-purple, infiltrated with blood.
XVIII.....	Oppolzer: Allg. Wien. Med. Zeit., 1858, xlv. Mediz. Neuigk., 1859, ix. 105. Wiener. Med. Woch., 1867, vii. 7.	M.	Adult, young	Strong.	Sudden cardialgia, without known cause, becoming violent on strong, epigastric pressure. Constant bilious vomiting, obstinate constipation. High fever, quick pulse, collapse. Death in 3 days or more. No evidence of poisoning. Diagnosis, perforating, gastric ulcer.	Pancreas at least doubled in size, dark-red. Hemorrhage between the lobules, and much extravasated blood in the vicinity of the pancreas, between the mesenteric folds.
XIX.....	Hooper: Beale's Arch. of Med., 1860, ii. 282.	M.	44	Active, fat, florid, temperate.	Sudden, severe pain below left breast, nausea, constipation, tympany, weak pulse. 2d day: Black vomit, dejection (alvine), exhaustion. Death in collapse on the third day.	Pancreas enlarged, hard, friable, contained several small, scattered extravasations of blood. The seat of several lobules occupied by large lobules of fatty matter, from which much margarine crystallized out. Very many, small, granular cells in the interval between follicles.
XX.....	Hilty: Corresp.-Bl. f. Schweiz Aerzte., 1877, vii. 666.	M.	30	Strongly built, fat, looked fond of spirits. In past few years frequent palpitation and occasional dyspnœa.	Sudden, abdominal fulness and tension attributed to new beer. Anxious, restless, uncomfortable. Feeble pulse, rapid breathing, cold sweat, subnormal temperature. Then abdominal pain, distended, tympanitic, upper abdomen. Nausea. 2d day: Collapse, spontaneous dejection, no fever. Sudden, violent delirium. Diagnosis, peritonitis from perforation. Death in 36 hours.	Pancreas doubled in size, firm, dark-violet. Extensive interlobular, hemorrhagic infiltration. In the head many nodular hemorrhages as large as cherry-stones, marked bloody infiltration of the peripancreatic tissue.
XXI.....	Guillery: Ueber d. Entz. d. Pankreas. Inaug. Diss., 1879, 26.	M.	....	Intemperate.....	In delirium tremens for a few days, then death.	Pancreas trebled in size from presence of fat-tissue within and around the gland. Minute hemorrhage in places. Microscopic examination showed hemorrhage between the cells, and a small-celled infiltration in the interstitial tissue. A peripancreatitis with gradual extension into the parenchyma.
XXII.....	Farge: Bull. Soc. de Med., 1880-82, N. S., viii. 188.	M.	42	Fat, temperate. Has had repeated attacks of severe abdominal pain, with bilious vomit. Watery vomit every morning for some time, and before present attacks.	Severe abdominal pain, worst in left side on palpation. No vomiting. Subnormal temperature. Abdomen tympanitic, distended, especially below navel. 2d day: Pain less, pulse weak. Death.	In head of pancreas a cavity with butter-like contents. A hemorrhagic mass in the tail, apparently the starting-point of a peritonitis, along the pancreas. Omentum thickly strewn with small, dirty-white, rounded, flattened patches, composed of cheesy-degenerated fat.
XXIII.....	Whitney: Boston Med. and Surg. Jour., 1881, cv. 592.	M.	Adult.	Robust; occasionally easily relieved, painful indigestion. A year ago jaundice, lasting two and one-half months, accompanied with some epigastric pain.	Epigastric pain, unable to continue occupation. 2d day: Symptoms of peritonitis with great prostration. Death on the following day.	Pancreas dirty-red, containing brownish-black nodules, mottled with opaque white spots. The microscope showed diffuse blood, and amorphous clumps of the same. The white spots due to short, staff, or spindle-shaped crystals in the fat-tissue. Outline of gland-cells lost, nuclei indistinct. Peritoneum reddened.
XXIV.....	Balser: Virchow's Arch., 1882, xv. 525.	M.	54	Enormous quantity of subcutaneous fat.	Sick for 2 or 3 days before death with slight, gastric difficulties. Soon followed by vomiting, symptoms of peritonitis and collapse. Diagnosis, internal strangulation.	Pancreas enlarged, soft, pale, dirty-yellow, speckled with numerous opaque-white streaks and spots, also dark-brown and reddish-black spots. Numerous ducts filled with blood-clots. Head of pancreas infiltrated with blood, and surrounded with clotted blood. Numerous hemorrhagic patches in the mesentery. Also opaque, bright-yellow patches, up to the size of a cherry-stone in the subperitoneal fat of the abdominal walls, and in that of the omentum and mesentery.
XXV.....	Haidlen: Cbl. f. Gyn., 1884, viii. 609.	F.	33	During first pregnancy much gastric disturbance and headache. In the last three months violent attacks of abdominal pain, suggesting impending perforation. Slow recovery. Two attacks during the five weeks after delivery.	Sudden, violent pain near pylorus, 37 days after delivery. Occasional vomit, some collapse, no fever. Sensitive epigastrium, abdomen moderately distended. The violent, epigastric pain persisted, meteorism took place. Collapse and death in 5 days.	Pancreas enlarged, almost wholly transformed into a brownish-red, bloody mass. The microscope showed a small-celled infiltration and hemorrhage which may have continued for some days. Duct somewhat dilated. Adjacent omentum slightly suffused with blood.
XXVI.....	Eichhorst: Eulenburg's Real-Encyclopädie, 1885, ii. 434.	....	....	.....	The patient died of ileus, ...	There was a hemorrhagic pancreatitis and peripancreatitis. The pancreas was as large round as a man's arm, and was so wedged between the spleen and the duodenum as to completely obstruct the latter.
XXVII.....	Amidon: Boston Med. and Surg. Jour., 1886, cxv. 594.	M.	Adult.	In perfect health..	Sudden nausea, vomiting, and slight diarrhœa. Some hours later severe gastric and abdominal pains and cramps. 2d day: Pains more frequent, intense thirst; collapse. Slight albuminuria. 3d day: No dejection. Subnormal temperature. Unexpected death on the fourth day.	Pancreas enlarged, hard. Between it and the duodenum, encroaching on the former, but adherent to both, was a flattened mass of blood an inch and a half in diameter.
XXVIII....	Pinkham and Whitney: MS. Notes, 1886.	M.	40	For a year or more general malaise and lack of strength, attributed to indigestion.	Epigastric pain, vomiting, weak heart. Death on the sixth day, preceded by cessation of the pain and vomiting.	Pancreas very large, on section, dark-red, streaks, and patches between the lobules. The fat tissue of the abdomen, especially near the pancreas studded with opaque, white spots of fat-necrosis, with a well-defined, blackish edge. Colonies of micrococci found near these spots.
XXIX.	Osler and Hughes: Trans. Phila. Path. Soc., 1887, xiii. 24.	M.	58	.....	Intense epigastric pain for several days. Sensitive epigastrium, haggard, emaciated. Cancer of stomach suspected. Found asleep after breakfast with Cheyne-Stokes breathing, almost imperceptible pulse. Death in less than 3 hours after discovery in the above condition.	Universal, interstitial, pancreatic hemorrhage, with clots in the tail. In the body of the gland the acini appeared as grayish-white areas surrounded by the dark-red hemorrhagic exudation. Increased round-cells in the semi-lunar ganglia, whose ganglion-cells were cloudy and indistinct. Œdematous Pacinian corpuscles behind duodenum and pancreas.
XXX.....	Hirschberg: Berl. Klin. Woch., 1887, xxxiv. 287.	F.	56	Very fat.....	Attacked with vomiting, abdominal pain; complete obstruction. A swollen, intestinal convolution to be felt in the right side. On the 4th day, sudden collapse, mind clear, abdomen distended, very painful, no palpable tumor. Laparotomy. Death 5 hours later.	Pancreas greatly enlarged, black from hemorrhage, fatty degenerated. General peritonitis with adhesions, and hemorrhagic exudation. Yellowish-white spots, up to the size of lentils, were seen beneath the parietal and visceral peritoneum, both at the operation and after death. They were composed of crystalline, fatty acids.

Seventeen Cases of Hemorrhagic Pancreatitis—Continued.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
XXXI.....	Birch and Hirschfeld: Lehrb. d. Path. Anatomie 3te Aufl., 1887, ii. 639.	M.	38	.....	Sudden, violent, colicky pains above the navel. Soon, high fever, delirium, copious green vomit, and death on the 2d day.	Pancreas markedly enlarged, dirty, brownish-red color. On section, dirty, grayish-red plugs were squeezed from the lobes and lobules. The microscope showed the interstitial tissue infiltrated with round cells, and red blood-corpuscles. The epithelium enlarged, granular, in many acini transformed into a finely granular detritus, a bloody, ichorous fluid in the pancreatic duct. Considerable swelling, hyperæmia, and ecchymosis of the duodenum and jejunum.
XXXII.....	Birch and Hirschfeld: Op. cit.	M.	42			
XXXIII....	Putnam and Whitney: MS. Notes, 1888.	M.	48	Abundant and fat tissue. Hemiplegic for several years. Has had several attacks of gastric pain, not lasting more than a day.	Awoke with severe gastralgia, vomiting, later collapsed. 2d day: Restless, but comfortable with morphia. Hiccough, vomiting some dark, red lumps. 3d day: Rapid breathing, cyanotic, collapse. Death.	Pancreas doubled in size. On section, dark-red, mottled with opaque, white spots. Fat-tissue near pancreas, and in root of mesentery discolored red. Mesenteric fat-tissue showed numerous opaque, white spots. The fat-tissue in places discolored; soft, and foul-smelling. Thrombosis of splenic, pancreatic, and mesenteric veins. No infiltration about semi-lunar ganglion.

They are twenty-two in number. One was of recent occurrence in Boston, for the notes of which I am indebted to Drs. Sears, Thompson, Jones, and Whitney.

The more detailed history of Case LV. is as follows: The patient was thirty-nine years of age, rather fat, intemperate. For a year or two before her fatal illness she had suffered more or less from poor appetite, distress after eating, wind in the stomach, and costiveness.

She was seized with sudden epigastric pain, without known cause, followed by vomiting, and the bowels were constipated. On the following day the pain became worse, but was somewhat relieved after vomiting. The next day, after a dinner of roast goose and cabbage, the pain became much aggravated. It was intense on the fourth day, and there was constant hiccough and vomiting. The epigastrium was sensitive, and the abdomen swollen. Pulse, 120; temperature, 103.4° F. She remained in this condition for several days, without any movement of the bowels, and intestinal obstruction was suspected. Castor-oil finally produced a dejection which was followed by a lowering of the pulse and temperature.

For nearly a fortnight she was not seen by a physician, and she was then admitted to St. Monica's Home, where she remained two weeks. During her stay she was dull and stupid, suffered from moderate epigastric pain and sensitiveness, nausea and vomiting, and inability to eat solid food. The skin was not hot to the touch. Pulse, 80. Her bowels were kept open by laxatives or enemata. There was a trace of albumin in the urine. The abdomen was full and rounded, and nothing abnormal was discovered on palpation. During the latter part of her stay she was able to sit up, daily, for a short time. She left the Home without the knowledge of the physician, walked some distance, and was supposed to have drunk to excess.

Three days later she was seen by Dr. Sears, who found her suffering from severe pain in the right hypochondrium and epigastrium, with marked prostration. Her thirst was intense, but she immediately vomited everything swallowed. There was constant expectoration of thick, frothy mucus. Pulse, 120; temperature, 99.4° F. The abdomen was distended, the walls rigid. There was especial prominence of the epigastrium and right hypochondrium. This condition persisted during the three following days, at the end of which she was taken to the Massachusetts General Hospital, where she died in the course of a few hours, at the end of the seventh week of her illness.

Dr. Whitney, who made the post-mortem examination, found the pancreas of normal size and density, in general of an opaque-gray color.

At the lower part of the head was a trabeculated cavity with dirty-green, shreddy walls, and containing cheesy, necrotic material. A large branch of the duct, with a ragged edge, opened directly into this cavity. Its wall, near the cavity, was green and soft. The main duct was intact, but contained, near its outlet, a small quantity of dirty-brown, viscid fluid. The parapancreatic fat-tissue formed a part of the wall of the cavity above mentioned; near the splenic end of the pancreas was a hole in the fat-tissue, as large as a walnut and containing a dirty-green fluid. Elsewhere in the neighboring fat-tissue, and in that of the mesentery, meso-colon, and posterior abdominal wall, were numerous opaque-white, pap-like nodules from the size of a pin-head to that of a pea. They were, at times, aggregated in clumps; the contents could be squeezed out. The smallest nodules were frequently surmounted by an injected border.

There was nothing abnormal in the portal vein or its immediate radicles. The liver was in a condition of brown atrophy, and there were minute, pale-yellow calculi in the gall-bladder and common duct. There was no evidence of a general peritonitis, but on cutting through the meso-colon the stomach and colon were found slightly adherent. The microscopic examination of the fat-tissue showed characteristic necrotic patches with a margin of round-celled infiltration. Also occasional small abscesses and more diffused infiltrations of leucocytes.

In addition, occasional circumscribed, round spots were seen, composed of more or less elongated and fat-cells, enclosed within a fibrous border. The cells varied in size, some being considerably larger than fat-cells and containing several nuclei, while the smallest had a diameter four times that of a red blood-corpuscle. These patches suggested a lymph-vessel plugged with desquamated and œdematous endothelium.

Dr. H. Jackson, under the supervision of Dr. Ernst, made a bacteriological analysis of the necrotic fat-tissue from the above case. From Dr. Ernst's report it appears that four varieties of bacteria were isolated:

1. A liquefying, fluorescent organism, which proved to be a fine, short rod, half the size of the bacillus of tuberculosis.

2. An organism closely resembling the staphylococcus pyogenes citreus, both in the manner of its growth and in its microscopical appearances.

3. Very short, rather thin, non-liquefying rods, which formed thin, grayish, almost translucent, and much-wrinkled pellicles on the surface of the gelatine and agar-agar, around the mouth of the needle-track.

4. The only organism found in large numbers. The cultures grew as finely beaded colonies along the needle-track, with a flat, pearl-gray top extending two or three millimetres over the surface of the nutrient material. Microscopic examination showed the organism to be composed of very short, thick rods, resembling somewhat the appearances found in one or two of the sections of the necrotic tissue. It did not liquefy the gelatine.

Twenty-two Cases of Suppurative Pancreatitis.

No.	Authority.	Sex.	Age.	Antecedents	Symptoms.	Lesions.
XXXIV....	Baillie: Morbid Anat., 1833, 221, 223.	M.	20	.....	General abdominal pain, nausea, sense of distention and weight in stomach after eating. Tendency to purge. Dropsy.	Pancreas a good deal enlarged and contained a considerable quantity of pus.
XXXV.....	Perle. De pancreate ejusque morbis, Diss. Inaug. Berl., 1837, 33.	M.	Adult.	Feeble, scrofulous, phlegmatic.	Dull epigastric pain for several weeks, then becoming violent, with nausea; offensive, loose stools; quick pulse, dry skin, sensitive epigastrium. Temporary improvement. Return of diarrhœa, fever, emaciation, weakness. Death at end of more than four months.	Pancreas in part hardened, in part full of pus. The pus had escaped into the abdomen. Other organs normal.
XXXVI....	Fletcher: Prov. Med. and Surg. Jour., Lond., 1848, 20.	....	Adult.	Corpulent, apparently much addicted to food and drink.	Great epigastric pain, distention after meals, continued dull pain, extending into both hypochondria above navel, relieved by purgatives, vomiting, constipation. Progressive emaciation and debility. Stools finally fetid, bloody. Temporary improvement, hectic, and death after nine months of illness, and four months in house. Intestinal obstruction suspected.	Enlarged pancreas formed a purulent mass without healthy structure. Its[t] extremity had ulcerated into the duodenum at lower curvature, through which pus must have passed into the intestine. Liver enlarged, spleen normal.
XXXVII...	Kilgour: Lond. Journal of Medicine, 1850, ii. 1052.	M.	41	Indolent, large eater, fond of sweets. For some years attacks of bilious dyspepsia. Last attack seven months ago, did not recover as usual.	Emaciated, feeble, dispirited, restless; frequent vomiting, eventually of thin ropy mucus. Sensation of distended stomach and bowels, in which much gas. No appetite, no thirst, sluggish bowels, consistent stools, unmixed with bile and very fetid. No pain nor sensitiveness, nor tumor. Left abdomen dull, tympany in right abdomen and over stomach. After two months of slight downward tendency, frequent chills and fever. Region between navel, lower border of stomach, and left flank dull, doughy, inelastic, not sensitive. After two weeks chills ceased and a resistant sore spot appeared above navel and at the left. Œdema of feet and legs. Death after eleven months.	Pancreas much enlarged, envelopes thickened. Entire gland formed a trabeculated cavity filled with creamy pus and a few cheesy masses about the size of a bean. The duodenum contiguous to the pancreas broke into pultaceous shreds, even on cautious handling. Spleen enlarged one-third. Despite extreme emaciation a half inch of fat in the abdominal wall.
XXXVIII..	Riboli (Gazz. Sard., 1858): Schmidt's Jahrb., 1859, cii. 177.	F.	54	Robust. Some months ago an attack of disturbed digestion with loss of appetite, flesh, and strength; chilliness, morning belching; thin, viscid, liquid vomited. Recovery.	Recurrence of antecedent symptoms, with deep-seated, dull pain, pyrosis, slight jaundice, swollen epigastrium. Alternate diarrhœa and constipation; stools white, slimy, not offensive. Gradual loss of flesh and strength. Death.	Pancreas wholly suppurating. Spleen natural. Gall-bladder full of bile.
XXXIX...	Klob: Œster. Zeitschr. f. pr. Heilkde., 1860, vi. 529.	F.	64	....	.....	Upper part of pancreas a dense gray callus, in which a few remains of gland substance and round cavities, up to the size of peas, filled with thick, white fluid; also, several small pus cavities. In the lower part of the pancreas an abscess as large as a walnut. The duct narrowed at the mouth, gradually widened toward the tail. Posterior wall of the stomach firmly adhered to pancreas, and contained a submucous abscess.
XL.....	Drasche: Ber. d. k. k. Krauhenaust. Rud-Stift in Wien, 1868, 301.	M.	23	Well.	Severe gastric pain without cause, loss of appetite, sluggish stools, slight fever, sensitive epigastrium, rapid emaciation. In the course of a fortnight violent paroxysms of stabbing pain, spreading laterally from the epigastrium, which was swollen, tense, and tympanitic. Paroxysms attended with transient collapse. In the fourth week a feculent diarrhœa, which suddenly became thin, profuse, watery, with nausea and bilious vomit. After decided improvement, fever and diarrhœa returned in the seventh week, and the abdomen became much distended. The tympany increased, there was occasional hiccough, progressive weakness, extreme emaciation, and death on the sixty-fifth day.	Pancreas large, firm, yellowish-red. Sclerosis of peripancreatic tissue. On section several abscesses, some larger than a bean, at times communicating by sinuous tracts, two of which open into the adherent posterior wall of the stomach, and two into the duodenum. Spleen of normal size, firm, pale red. Splenic vein obstructed by a reddish-yellow thrombus, in front of which the vein-wall was shreddy and its cavity communicated with a large abscess. A lumbricus lay half in the vein and half in the abscess, and in a sinuous passage leading from it to the duodenum. An abscess as large as a hen's egg in the left lobe of the liver. Fibrinous peritonitis, especially in upper abdomen.
XLI.....	Roddick: Canada Med. Jour., 1869, v. 385.	M.	30	Intemperate. Much exposed when drunk, and then has diarrhœa. Has had two attacks of intermittent fever. Chronic cough for two years. Under treatment for syphilis.	After two days of constipation slight epigastric pain and vomiting, thirst, hot skin, no appetite. The bowels were moved freely. A chill occurred, followed by fever, chills, and diarrhœa toward the end of the week, then slight jaundice, persistent chills, and diarrhœa, and death in a collapse on the twelfth day.	Pancreas firmly adherent. On section of the enlarged head an abscess opened, the walls thick; contents, an ounce of pus. The dilated duct in the head held several calculi. Spleen weighed 11½ ounces. Lungs phthisical, and containing a central chocolate-colored nodule from which pus escaped.
XLII.....	Nathan: Med. T. and Gaz., 1870, ii. 238.	M.	25	Catarrhal symptoms and great debility for two weeks.	For two days gastric irritability, nausea, constipation; then incessant hiccough. Epigastrium distended, tympanitic, no pain, no tenderness, constant copious vomiting of thin, brownish, stringy fluid; no jaundice; increasing loss of flesh and strength. Death from exhaustion in six days from the onset of the symptoms of gastric disturbance. Diagnosis, ileus.	Pancreas large, head indurated, mortar-like. Duodenum closed by pancreatic pressure, coats thickened. Small omental hemorrhages. Distended gall-bladder.
XLIII.....	Smith: Dublin Jour. Med. Sci., 1870, 201.	M.	....	....	.....	Pancreas closely connected with neighboring organs. Splenic end contained a small abscess, with thick greenish-yellow pus. Several small lymphatic glands near duodenal end contained similar pus. Abscess in the diaphragm above the spleen.
XLIV.....	Frison: Marseille Méd., 1875, xii. 257.	M.	30	.....	Continued fever, severe abdominal pain at level of spleen, which was supposed to contain an abscess. Death in a month.	Abscess of pancreas surrounded with adhesions.
XLV.....	Frison: Loc. cit.	M.	28	Delicate; suffered from hard work and extra hours.	Loss of appetite, epigastric pain, jaundice, no fever. In third month pain in right hypochondrium and shoulder; swollen abdomen, testicles, and feet. Sudden increase of appetite and thirst, abundant saccharine urine. In the tenth month intense jaundice, extreme emaciation, great weakness, lower abdomen dull, upper abdomen distended and tympanitic. Diabetes persisted, return of fever. Death in coma at end of ten and a half months.	Pancreas enlarged threefold, indurated, infiltrated with pus. A large collection of thick, yellow pus in the tail. Numerous small abscesses in the left lobe of the liver. Enormous dilatation of the common bile-duct. Spleen not enlarged.
XLVI.....	Friedreich: Ziemssen's Handb. d. Sp. Path. u. Ther., 1875, vii. 2, 243.	M.	40	.....	An attack of severe abdominal pain, without cause, followed by tense tympanitic abdomen, which was sensitive. Frequent regurgitation and bilious vomit, constipation, high fever. Death in the course of a week.	Pancreas enlarged threefold, reddened, consistency increased, studded with hundreds of abscesses up to the size of beans, many projecting had burst into abdomen. General fibrino-purulent peritonitis, especially in the upper abdomen.

Twenty-two Cases of Suppurative Pancreatitis—Continued.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
XLVII.....	St. George's Hosp. Rep., 1877-78, 1879, ix. 95.	M.	....	Strong; temperate. Dislike for fatty food. Sick-headaches, left inguinal hernia.	After a month of cough and dyspnœa, six months ago, came diarrhœa, wasting, loss of appetite, and jaundice. After seven weeks a month of considerable œdema. For ten days epigastric and interscapular pain. Death from exhaustion after five months of abdominal symptoms.	Head of pancreas enlarged. A diffused abscess followed the course of the ducts and opened into the lesser omental cavity which was full of pus, and communicated with the duodenum. Fibrino-serous peritonitis. Thrombosis femoral vein. Cheesy apices, cirrhotic distended bile-ducts.
XLVIII	Shea: Lancet, 1881, ii. 791.	F.	29	Fifteen months ago pain in region of liver, increasing and shooting; no nausea, poor appetite, bowels regular, fæces dark.	Jaundice for two weeks, tenderness over gall-bladder, cough, disturbed sleep. After two weeks apparent convalescence for four days, then return of pain over gall-bladder; nausea, bilious vomit, jaundice; restless; rapid breathing, unconscious. Death in thirty-six hours.	The enlarged and hard pancreas contained an abscess. A round worm, seven inches long, lay partly in the duodenum, partly in duct; large fatty heart, pale kidneys. Large, pale, soft liver.
XLIX.....	Fraenkel: Ztschr. f. klin. Med., 1882, iv. 277.	M.	58	A year ago loud belching; abdominal fulness, no sensitiveness. Nine months ago pale, sensitive epigastrium; black, tarry stools. Recovered from these symptoms, but was pale and emaciated. After five months another attack of intense gastric disturbance lasting a fortnight. Then improvement and gain in weight.	After an error in diet, vomiting and severe abdominal pain. Swollen, sensitive abdomen. Pains in both hypochondria. After four days increasing meteorism, fever, return of vomit, sleeplessness, progressive weakness, collapse, and death on the eleventh day.	Pancreas, swollen, anterior surface dotted with numerous yellowish-white prominences, up to the size of hemp-seed, alone and in groups, forming cavities with smooth walls and pap-like contents. A group of these, gray, gangrenous, covered with shreddy peritoneum. The contents of these cavities were partly, granular corpuscles and detritus. The smallest had a wall of small-celled infiltration, similar faces on section, also narrow and broad bands and diffused growth of fat-tissue. Similar prominences in the transverse mesocolon and mesentery, in the former a circumscribed necrosis with floating shreds, and fresh peritoneal adhesions. Abundant subperitoneal fat.
L.....	Moore: Trans. Lond. Path. Soc., 1882, xxxiii. 186.	M.	25	.....	Obscure symptoms of peritonitis.	Pancreas extensively destroyed by suppuration. The remaining splenic end infiltrated with pus, showed a ragged surface, forming part of the wall of an abscess, bounded below by the lowest four inches of the ileum, and above by the stomach, spleen, abdominal wall, and coils of intestine.
LI.....	Moore: Loc. cit.	M.	74	.....	....	Head of the pancreas partly broken down, found one wall of an abscess elsewhere, bounded by peritoneal adhesions.
LII.... ...	Moore: Loc. cit.	M.	35	.....	Slight jaundice.	A large part of the head of the pancreas destroyed by an abscess bounded by pancreas, duodenum, and under-surface of stomach. The dilated common duct communicated with the abscess, and the latter opened into the peritoneal cavity and invaded the pancreatic and duodenal artery.
LIII.....	Musser: Am. Jour. Med. Sci., 1886, N.S., xci. 449.	M.	42	Intemperate; exposed to hardship.	For some weeks increasing debility. One attack of vomiting, marked ascites. For the next twenty-five days dull, listless, without appetite; fever, pain. Ill-defined epigastric tumor, not sensitive. Abdomen tapped, refilled in eighteen hours.	In the head of the pancreas an abscess as large as an orange. The rest of the gland dense, containing numerous pus pockets. Ducts dilated. The large abscess opened into a pus cavity, bounded by posterior wall of stomach, pancreas, duodenum, transverse colon, and peritoneum. Portal vein filled with a puriform thrombus extending into hepatic, splenic, and mesenteric veins. Slight cirrhosis; small, soft spleen. Recent peritonitis; bronzed skin.
LIV...	Bamberger: Wiener Clin. Woch., 1888, xxxiii.; Allg. Med. Centr. Zeit., 1888, lvii., 1870, 1886.	M.	20	....	Ate a probably putrid sausage. Sudden nausea, violent vomiting, prostration, alternating heat and cold, severe headache. The next day chill, cutting pains in abdomen, diarrhœa. On the fifth day high fever, meteorism, dilated gastric and ileo-cæcal regions. A week later jaundice. After five days the liver became enlarged, painful, and sensitive; the abdomen eventually distended and tense; the stools thin and pap-like; urine frequently contained peptones, one or two daily chills with atypical and abrupt changes of temperature. Eventually repeated watery vomit; hiccough. Death in collapse at the end of the sixth week.	Head of the pancreas contained an abscess as large as a hen's egg, filled with greenish-yellow pus. The greatly enlarged liver agglutinated to the diaphragm, anterior abdominal wall, and stomach; numerous abscesses present, the largest the size of a hen's egg, also dark violet nodules. Vena portæ almost obstructed by a brownish-red thrombus, continued into the splenic vein. Behind the pancreatic abscess the portal vein wholly obstructed, the thrombus reddish-gray, in a state of puriform softening. Spleen 6 by 3½ inches, pulp not readily scraped away; dense, brownish-red. Recent fibrino-serous peritonitis.
LV.....	Mass. Genl. Hospital Records and MS. Notes, 1888, v. 131.	F.	39	Intemperate. Has suffered for a year or two from poor appetite, distress after eating, pain in stomach; constipation.	Sudden epigastric pain, vomiting, constipation. In the course of a few days after an error in diet the pain became intense, accompanied with fever. There was constant hiccough and vomiting. The abdomen became swollen, and the epigastrium sensitive. The constipation persisted, and intestinal obstruction was suspected. Six days before death, after indulging in alcohol, his symptoms became aggravated, and death occurred on the forty-eighth day.	The head of the pancreas contained a trabeculated cavity with green, shreddy walls, which communicated with the parapancreatic fat-tissue, a branch of the duct with green and friable walls opened into the cavity. In the fat tissue at the splenic end of the pancreas was a cavity containing a dirty green fluid. Multiple nodules of fat necrosis are present, also peritoneal adhesions between stomach and transverse colon in the omental bursa. No general peritonitis. Nothing abnormal in the portal vein or its branches.

Of twenty-one patients, seventeen were males and four were females; all were adults, whenever ages were mentioned, and in eighteen cases the age was given as follows:

Years of age.	Number of cases.
From 20–25	3
" 25–30	4
" 30–35	2
" 35–40	2
" 40–45	3
" 45–50	0
" 50–55	1
" 55–60	1
" 60–65	1
" 65–74	1

Previous attacks of indigestion, of greater or less frequency and severity, were present in about one-fourth of the cases. These attacks were usually regarded as gastric or bilious. One patient suffered from sick headache, while another was subject to diarrhœa during his drinking-bouts. Three were distinctly intemperate, two might be regarded as gluttonous, and one was exposed to hard work and extra hours.

The immediate attack was precipitated in two instances by errors in diet, in the one case a probably putrid sausage having been eaten. The attack was greatly aggravated in a third case by a dinner of roast goose and cabbage. Two weeks of catarrhal symptoms with great debility were the antecedents of another case.

A striking feature in the history of these cases of suppurative pancreatitis is the tendency of this affection to become chronic. Of fourteen cases six were fatal in the first month, three during the second month, and five at

various periods between four and eleven months. Death might take place at the end of the first week, and even the more chronic cases often began with distinctly acute symptoms.

It is therefore desirable, in the consideration of this series of cases, to group them with particular reference to the rapidity of their course.

The cases of acute suppurative pancreatitis usually began suddenly, with severe, generally intense, gastric, epigastric, or abdominal pain, vomiting, and sometimes great prostration. The vomiting might be incessant and distressing, or it might give temporary relief to the pain. The ejected fluid was sometimes stringy and brown. The bowels were usually constipated, although diarrhœa might occur within the first twenty-four hours. This latter symptom was not infrequent at a later date of the disease.

Fever, usually slight, was the next conspicuous symptom, being manifested about the third day. At the same time the upper abdomen, especially the epigastrium, was likely to become distended, tympanitic, and sensitive. Hiccough, sometimes quite obstinate, was not infrequent at this stage, and occasional chills were to be met with. The abdomen, in general, then became moderately swollen, tense, and tympanitic.

With the violent onset and persistence of these symptoms death might occur, perhaps, in the course of a week or more.[69] The pancreas then was markedly enlarged, reddened, and studded with hundreds of small abscesses, many of which had burst into the peritoneum. The associated fibrino-purulent peritonitis was most marked in the upper abdomen. In the second case,[70] where death resulted in eleven days, the attack was apparently recurrent in a corpulent person who had suffered for a year from symptoms which might be attributed to pancreatic disease. There were found in the pancreas numerous small, yellowish-white prominences, alone and in groups, with soft, pap-like contents. They were present on section as well as superficially. The contents were fatty-degenerated cells and detritus. The wall of the smallest cavities was infiltrated with round cells, while that of the others was smooth. A group of these prominences were grayish, discolored, gangrenous, the superficial peritoneum being perforated and shreddy. Similar nodules were found in the mesentery and in the transverse meso-colon. In the latter was a circumscribed necrosis with floating shreds and fresh, peritonitic adhesions. The pancreas was irregularly traversed by narrow and broad bands and by a diffused development of fat-tissue. Not only does the clinical history of this case suggest a recurrent and finally fatal attack, but the pancreatic lesions also point to a long-standing process. Fibrous bands, fatty-degenerated cells and smooth-walled cavities filled with detritus favor this view. The description of these nodules suggests that many of them were probably foci of fat-necrosis, with gangrenous sloughing of the subjacent peritoneum.

An acute, suppurative pancreatitis, however, very rarely terminates at this early date. The symptoms already described may persist for three or four weeks, with progressive emaciation and debility, and death occur from exhaustion. Under such circumstances the simple abscess has been found surrounded with adhesions.

In another series of cases, beginning equally violently, there may be frequent chills and irregular, atypical, often high, fever, the maximum temperature being 105.8°. Slight jaundice may be associated. The pains extend into the hypochondria, and may spread from this point downward.

The liver, perhaps the spleen, may be palpably enlarged—the symptoms are conspicuously those of blood-poisoning, and the patient dies collapsed in the sixth or seventh week. An abscess as large as a hen's egg, filled with greenish-yellow pus, may then be found in the pancreas. Also a pylephlebitis, apparently the result of the pancreatic abscess and associated with multiple abscesses in the liver, and acute peritonitis.[71] Death at the end of seven weeks may result from the extension of the pancreatic abscess to the parapancreatic fat-tissue, with the production of multiple nodules of fat-necrosis.[72] In this case the symptoms of epigastric pain, vomiting, constipation, and swelling were interrupted by a period of several weeks of comparative comfort, to be followed by marked prostration, incessant vomiting, severe epigastric pain and fever.

Another event in the history of acute, suppurative pancreatitis is to be found in the course of the third or fourth week of the tense and swollen, painful and sensitive, upper abdomen which follows the pain, vomiting, constipation, and fever. A diarrhœa then becomes conspicuous, perhaps preceded by violent paroxysms of lancinating pain shooting laterally in the epigastrium, producing temporary collapse.

The loose stools may be thin, yellow, and feculent at the outset and then become profuse and watery. This symptom may then subside, with a lowering of the fever and a general improvement, to recur after a few weeks with fever and abdominal distention, progressive emaciation and increasing weakness, ending in death in the tenth week.

Several small abscesses have then been found in the enlarged and firm pancreas, with sclerosed peripancreatic tissue. Communicating sinuses unite these abscesses and open into the adherent stomach and duodenum. A splenic thrombo-phlebitis and a hepatic abscess may be associated, also a fibrinous peritonitis, especially marked in the upper abdomen.[73]

The early symptoms may be less severe and the disease be announced by progressing weakness and emaciation. Loss of appetite, slight jaundice, perhaps diarrhœa, may occur. There may be neither fever nor pain, or there may be obscure symptoms of peritonitis. Finally, anasarca or ascites becomes apparent, and death occurs from exhaustion, perhaps at the end of five months. The pancreas may then contain a diffused abscess, following the course of the ducts and opening into the cavity of the lesser omentum, which was filled with pus, and in its turn emptying into the duodenum through a sinus in the mesentery, these conditions being associated with a fibrino-serous peritonitis. The pancreatic abscess may extend, at an earlier date even, to the omental cavity, thus forming a great pus-cavity extending as low as the lowermost coils of the ileum, and walled in by adherent intestines and stomach. The greater part of the pancreas may be destroyed. The common duct may open abruptly into the abscess of the pancreas, and leave it at the hepatic end. There may be an associated thrombosis of the portal vein continued into its primary sources, and the pancreatico-duodenal artery may be eroded, with hemorrhage into the cavity of the abscess. A recent peritonitis may be associated, and in one of these somewhat protracted cases, with extension to the omental cavity, a bronzed skin was present.

Finally, there are the most chronic cases, which extended over a period of nearly a year. As a rule no severe pain occurs at the onset, but the patient gradually becomes weak and thin; vomiting may be frequent, and a sense of distention of the stomach after meals or of epigastric pain be complained of. There may be little or no fever, or periods when chills and fever occur. The stools may be consistent, not colored with bile, and very fetid, or later they may be very offensive and mixed with blood. There may be a free communication between the pancreatic abscess and the duodenum, or the latter may break into pultaceous shreds when handled. The entire pancreas may be converted into a trabeculated cavity filled with creamy pus and cheesy masses, or it may be indurated and infiltrated with pus. In one of these protracted cases[74] diabetes appeared after the third month.

[69] Case XLVI. [70] Case XLIX. [71] Case LIV. [72] Case LV. [73] Case XL. [74] Case XLV.

Noteworthy in these cases of suppurative pancreatitis is the rarity with which a circumscribed tumor is to be found. A swollen, tympanitic epigastrium is the rule, and very rarely a circumscribed resistant spot was to be felt above the navel, to the left of the median line.

Jaundice occurred in less than one-fourth of the cases. It was then usually slight. Its intensity in one case was connected with abscesses in the liver and dilated bile-ducts.

Another fact of considerable importance is the, usually, small size of the spleen. The rule was that no enlargement was noticeable even in those cases in which the thrombotic obstruction of the splenic or portal vein was recorded. The small spleen was usually of normal density.

From the above consideration it is evident that there are cases, few in number, of acute suppurative pancreatitis which run a course similar to that described in connection with hemorrhagic inflammation. They may begin with equal suddenness, present the same grouping of symptoms, but are not so early fatal. They are more rarely associated with evidences of fat-necrosis, which were present in but two instances.

Although Klebs[76] regarded pancreatic abscesses, not arising from a peripancreatitis or from suppurating cysts, as of doubtful existence, it is apparent that this view is opposed by the evidence here recorded. It is also evident that the extension of an abscess from the neighboring lymph-glands to the pancreas is of extreme rarity. The only evidence in favor of this view is that offered by Portal[76] and in the case[77] reported by Smith. The possibility that a pancreatic abscess may be due to inflammation of the appendix is evident from Moore's case, although the connection between the two may have been through a mesenteric thrombo-phlebitis, arterial embolism, or through the coexistence of acute pancreatitis and appendicular inflammation.

The possibility that a pancreatic inflammation may be excited by the passage of a lumbricus into the pancreatic duct is admitted in connection with the appearances in Case XLVIII. It is still more probable, however, that the worm entered the pancreas after the establishment of the inflammation. Its presence there might be merely accidental, even taking place after death, as is likely to have been the fact in Case XL.

CARBONIC-ACID WATER AS A VEHICLE FOR CREASOTE.—The taste and odor of creasote are so disagreeable to many patients that physicians have in some instances been deterred from prescribing it, especially in the large doses in which it has been advised by German writers. It is true, when given in capsules the taste and odor are not perceived; but this form of administration is objectionable when large doses are given, because the drug then reaches the stomach in a concentrated form. Dr. J. Rosenthal advises the use of carbonic-acid water containing cognac as a vehicle for the creasote. This combination, he says, is comparatively tasteless, and obviates the disadvantages attending the administration of creasote in a concentrated form. The mixture is put up in bottles holding five and a half, ten and a half, and sixteen ounces. The smallest bottles contain from one and a half to three minims of creasote and seventy-five minims of cognac; the middle-sized bottles, six minims of creasote and two and a half fluid drachms of cognac; while the largest contain nine minims of creasote and three and a half fluid drachms of cognac. During the first week the patient is directed to take one of the smallest bottles after dinner and supper each day; during the second week he should take a half-bottle of the next stronger water after breakfast and dinner, but continue to take the weaker water after supper. The quantity of creasote which he takes may in this way be increased gradually until the maximum dose of twelve and a half minims a day is reached. —*The Medical and Surgical Reporter.*

A CLINICAL STUDY ON ALOPECIA AREATA, AND ITS TREATMENT.[1]

BY L. DUNCAN BULKLEY, A.M., M.D.,
NEW YORK.

ALTHOUGH not a dangerous affection, and one ordinarily thought of mainly in connection with cosmetic effect, alopecia areata may, and often does, cause an amount of annoyance and distress which is as hard to be borne as actual pain. While in some instances it may be but a transient affair, and may consist of but one or more small, perfectly bald spots, which are readily concealed by hair of ordinary length, in other instances it may prove most intractable, lasting years, involving large and conspicuous areas, and even removing every hair from the body, including eyebrows and lashes; in its fullest development it causes a very considerable disfigurement, and even in moderately severe cases the baldness is so striking that it becomes a veritable cross to the sufferer, from the attention it attracts and from the uncertainty as to the nature and cause of the affection.

It may be well, therefore, for us to give a little consideration to this complaint as it appears clinically among us, and to indicate the treatment most successful in remedying the disease.

I shall not attempt at all to enter into a discussion of the nature or causation of alopecia areata, which has been so ably presented by Robinson[2] in his article before the Ninth International Congress in 1887. The subject is a great one, about which much has been written in advocacy of its neurotic origin on the one hand, and of its parasitic nature on the other. A further discussion of the matter here would be fruitless, and foreign to the purpose of the paper, which is simply to present personal clinical experience in the disease, with an analysis of the cases which have been under my observation and care.

Alopecia areata is presented for treatment much less frequently than I had supposed, previous to making my inquiries into the statistics of cases of skin disease which had been under my care. In my first analysis of one thousand cases of skin disease,[3] I find but four instances of alopecia, and of these only one was recorded as alopecia areata, one of alopecia partialis, and the other two had no special designation. In my next series of cases analyzed[4] not a single instance of the complaint was recorded among 617 cases of skin disease; and in my third analysis[5] only one patient with alopecia areata was seen among 774 cases of skin disease. In a subsequent study and report on 8,000 cases of skin disease in private and public practice,[6] there were 46 cases of alopecia areata; of these, 32 occurred among 2,583 cases in private practice, 1.24 per cent., and but 14 cases were seen in public practice among 5,417 cases, or only 0.25 per cent. of all skin cases.

On examining carefully later records I now find data relative to 119 cases of alopecia areata, occurring among 12,725 cases of skin disease, seen in private practice, at the New York Hospital, and at the Skin and Cancer Hospital. I have excluded all of the earlier records of skin cases seen in other institutions, because the original data are not accessible at present.

The proportion of cases of alopecia areata to the whole number of patients is here seen to be 0.94, or not quite one per cent. But when we come to examine the records of cases seen in private practice as compared with

those seen in public institutions, the difference will be found very striking. Thus, among these 119 cases, only 32 were observed in public practice among 7,086 cases, it forming there only 0.45 per cent., whereas in private practice there were 87 instances among 5,639 cases of general skin disease, or something over 1.54 per cent. The reason for the larger percentage of cases occurring among the public cases now analyzed than among those previously referred to, is found partly in the fact that in the hospitals last mentioned the grade of patients is higher than in many other public institutions, approaching more nearly to the class treated in private practice.

It will be seen that in these statistics the proportion of cases of alopecia areata was more than three times greater in private than in public practice, namely, 1.54 per cent. to 0.45 per cent. This difference in relative frequency cannot be wholly attributed to the greater attention which would be paid to the complaint among the former class of patients, for the appearances presented by the bald, smooth, white patches are so striking that they cannot escape attention, and my experience has been that the plainer classes are often quite as solicitous about the disease, when present, as are the rich. I believe alopecia areata to be relatively much less frequent among the poor than among the rich, which is, in a certain measure, an argument against its supposed parasitic origin, and in favor of its neurotic nature.

In the large statistics gathered by the members of the American Dermatological Association, almost entirely or very largely from public practice, the disease forms only about 0.64 per cent., corresponding more to that observed by me in public practice. It seems, however, to be somewhat more frequent in other countries, as McCall Anderson [1] gives nearly two per cent. among his cases, and Crocker [2] says that his statistics yield about the same.

Referring now to the 119 personal cases already mentioned, we will find many points of considerable interest in them, as the histories of almost all of them have been preserved. The following table presents the ages of the patients when applying for treatment:

TABLE I.—*Ages of One Hundred and Nineteen Patients with Alopecia Areata.*

Age.	Males.			Females.			Grand total.
	Private practice.	Public practice.	Total.	Private practice.	Public practice.	Total.	
5 years and under	..	1	1	1	..	1	2
5 to 10 years	1	..	1	4	3	7	8
10 to 15 years	6	..	6	5	1	6	12
15 to 20 years	3	1	4	3	4	7	11
20 to 25 years	7	7	14	4	1	5	19
25 to 30 years	12	5	17	1	1	2	19
30 to 35 years	10	2	12	3	2	5	17
35 to 40 years	12	1	13	4	1	5	18
40 to 45 years	2	2	4	2	..	2	6
45 to 50 years	1	..	1	..	..	..	1
50 to 55 years	3	..	3	1	..	1	4
55 to 60 years	..	..	..	..	..	..	..
60 to 65 years	1	..	1	..	..	..	1
Unknown	1	..	1	..	..	..	1
Total	59	19	78	28	13	41	119

It will be noted here that the number of the males is almost double that of the females, seventy-eight to forty-one.

The ages of the patients will be found to vary greatly, from early childhood to over sixty years of age, but the disease is found to be relatively rare in either extreme of life. The youngest patient was a little girl of four and a half years, now under treatment, who had had the disease since a few months of age. The oldest patient was a gentleman of sixty-one, who had been affected several times; the first time thirty-nine years previously, the second time twenty years previously, and the third attack began six months before his visit.

[1] McCall Anderson: A Treatise on Diseases of the Skin, p. 44. London, 1887.

[2] Crocker. Diseases of the Skin, p. 609. London, 1888.

Taking the years in decades, it will be found that there were comparatively few cases during the first ten years of life, but ten patients in all; this number is relatively small, considering the large number of individuals living at that age. It is a little curious also that of these ten cases, eight were in females, whereas in the total statistics the males were so largely in excess; in the next decade the females were again in excess, by three. I think that the reason for the larger proportion of females during these earlier periods of life can only be explained by the greater delicacy of their nervous organism at this time, taken in connection with the nervous theory of the disease in question.

The third decade, that between twenty and thirty years of age, presents by far the largest share of all the cases of alopecia areata, namely thirty-eight, or almost one-third of the entire number analyzed. And here is seen another striking fact in regard to sex, namely, that during this decade the proportion between the sexes is exactly reversed from that which was observed in the first decade of life; namely, that the males are in very great excess, instead of the females. Thus, we find here thirty-one males to but seven females; namely, more than four to one; exactly the reverse of that seen in the first decade, when there were four females to one male. If any supposition or deduction can be drawn from so small a number of cases, is it not that during this busy period in men's lives, when the cares of life begin to press, it is most likely that a nervous affection of this nature should develop?

In the fourth decade, that from thirty to forty years of age, we find still a large proportion of the cases, namely, thirty-five, more than in the first two decades together. Here the males are two and a half times the number of the females, namely, twenty-five to ten, the figures still supporting the nervous theory of the affection. In the later periods of life the disease is seen to be very much less frequent—indeed, it is rarely met with after fifty years of age. We find, then, that no less then seventy-three patients, or over sixty-one per cent. of the cases, occurred between the ages of twenty and forty. A negative argument against the alleged parasitic nature of the complaint is found in this fact, as it is well known that vegetable parasitic diseases belong largely to early youth, and are comparatively infrequent in adult life.

In the preceding table the ages of the patients were given at the time when they first presented themselves for treatment; this, however, does not exactly represent the age at which the disease appears, for in some of the patients it had existed for a considerable time before applying for relief. The following table, (II.) gives the alleged ages at which the disease developed in those patients in regard to whom a record is found of the fact, namely, in ninety-three cases.

TABLE II.—*Age at which Alopecia Areata Commenced in Ninety-seven Cases.*

Age.	Males.			Females.			Grand total.
	Private practice.	Public practice.	Total.	Private practice.	Public practice.	Total.	
5 years and under	2	1	3	2	..	2	5
5 to 10 years	3	..	3	4	4	8	11
10 to 15 years	8	..	8	5	1	6	14
15 to 20 years	4	2	6	2	2	4	10
20 to 25 years	8	2	10	4	0	4	14
25 to 30 years	13	1	14	1	..	1	15
30 to 35 years	4	2	6	3	1	4	10
35 to 40 years	7	..	7	5	..	5	12
40 to 45 years	0	1	1	1	..	1	2
45 to 50 years	1	..	1	..	..	..	1
50 to 55 years	3	..	3	..	..	..	3
Total	53	9	62	27	8	35	97

In looking at this table we see that the figures still corroborate the deductions drawn from the preceding table. Thus, of the ninety-seven cases in which the age of the patient at the commencement of the disease was recorded, in no less than twenty-nine patients, or thirty per cent., it began between the ages of twenty and thirty years, and of

these twenty-nine patients, twenty-four were males and five were females.

Table III. exhibits the duration of the disease before the patient came under treatment. It would be very interesting to give also a table of the entire duration of the disease, but, unfortunately, so many of the cases pass from notice, especially in public practice, before a perfect cure is obtained, and so many patients are seen in consultation, or but a single time, that it is very difficult to secure accurate statistics on this point. From this table, however, we learn that the affection is by no means a brief or transitory affair, but that the baldness, which may begin with a single insignificant spot, may increase and remain, often resisting all treatment even for many years.

TABLE III.—*Duration of Alopecia Areata in Ninety-three Patients.*

Total	53	8	61	26	6	32	93

Of the cases here analyzed, namely, ninety-three, where the duration was recorded, thirty-five, or nearly half, had lasted six months before coming under treatment; in fourteen others the disease had existed between six months and a year; in eight it had lasted between one and two years; in seven between two and three years; and in nine between three and four years, and so on; while some cases are recorded as of twenty, twenty five, and even thirty years' duration.

Alopecia areata, however, will occasionally be seen to be quite self-limited, or rather to get well spontaneously without medical aid. In a number of instances among these cases there is record of former attacks, where the bald spots have become perfectly covered without treatment, in a varying space of time from a few weeks to some months; the disease has then again developed, perhaps, after an interval of months or years, persisting then, in spite of treatment, for some considerable time. In other patients, suffering from quite different skin affections, we also occasionally get the history of one or more attacks of alopecia areata which have recovered spontaneously, and not returned up to the date of observation. But in my experience this spontaneous recovery is relatively rare, and in the larger share of instances it is not permanent.

The longest period during which I have observed a case is in connection with that of a young gentleman now nearly thirty-nine years of age, whom I first saw something over twelve years ago. The disease had begun in him at two years of age, when the hair began to come out in spots, until within a year or two he had lost all the hair and eyebrows. He wore a wig until fifteen or sixteen years of age, there being almost no attempt at hair reproduction, when, after spending a little time at Richfield Springs, the hair reappeared over almost the entire scalp, and he began to grow beard and whiskers, which at nineteen years of age were full and natural. Affairs remained in this condition until he was twenty-six years of age, when alopecia areata appeared in the beard, and soon new spots developed, until, when seen nine months later, about one-fourth of the hairy surface of the face and scalp was bereft of hair. In spite of pretty diligent treatment the trouble remained, and increased until he became almost entirely bald on the scalp and face, including the eyebrows and lashes, and he lost the hair also from the body and limbs, including axillæ and pubes. From this relapse he has never recovered; for, although the hair regrows to a slight degree here and there, he is still obliged to wear a wig, and there is almost no reproduction of the hair on the face. He, however, after the first few months, has never been very diligent in treatment, and has always been burdened with a rather vexatious business, and has also had considerable depressing nervous influences in his family relations.

Among the cases here analyzed there occur thirteen cases—six males and seven females—in whom the disease was almost universal. Several of these recovered entirely; in one instance, a man acquired syphilis shortly after the hair had completely regrown from the alopecia areata, and within a few months the hair again fell, this time from the syphilis, in a very characteristic manner, quite different from that before presented, and again it regrew perfectly under anti-syphilitic treatment.

The limits of this paper do not permit of a further analysis of the cases, nor of the presentation of individual cases, many of which present points of very great interest, and I will pass to a brief consideration of the therapeutical aspect of the subject.

Successful treatment must ever depend upon a correct knowledge of the clinical history and nature of the disease, and a few words may be added in regard to this latter, without attempting, however, to enter the subject at all exhaustively.

From what has preceded it is readily seen that I believe in the nervous origin and nature of alopecia areata. I may say that I have examined a large number of the hairs taken from patients with this affection, as also scales scraped from the surface, and have always failed to detect any parasitic elements; and I may add that in no single instance has the disease been presented to me in a manner to show contagion, as occurs constantly in favus and ringworm, and no two of my cases occurred in the same family.

Time does not permit of the mention, or even of analysis, of the various researches on alopecia areata, and opinions concerning the disease. I may state, however, that Robinson, in the article referred to, shows pretty conclusively the untenability of the parasitic theory of the disease; but he also argues, though less forcibly, against its nervous origin. Robinson claims to have found the real cause of alopecia areata in micrococci, having "their seat specially in the lymph-vessels; that they give rise to inflammatory changes in the corium, and frequent coagulation of fibrine in the lymph- and blood-vessels." He believes that "the interference to the growth of the hair would seem to depend, partly at least, upon the thickened blood-vessel walls, and, in recent cases, also upon the presence of coagula in the arteries and lymph-vessels, interfering with the nutrition-supply. If an artery should be closed, the hair could fall out very suddenly in an area of considerable size, namely, the area supplied by that vessel; or a considerable extent of lymph-vessels could be clogged, and the same result could follow."

The theory is a plausible one, and if these observations as to the existence of micrococci deep in the corium are confirmed by others, it may possibly be found that they have some pathogenetic relations as to the ultimate causation of the disease. But, on the other hand, even if these foreign bodies were found to be present, it by no means follows that they are a primal cause of the disease in question. It is not claimed that they are acquired by infection from other cases, and the question arises as to whether they are not accidental, or a result rather than a cause of the disease under consideration. A theoretical argument has little worth in matters such as this, and at any rate we must wait further researches on the subject.

But even if these micrococci are an element of causation, the same arguments hold here as in other diseases, such as pneumonia, where they are detected, namely, that some condition of system or of the tissues is necessary in order that such microbes may find a footing and effect a development.

This brings us, therefore, to what I believe to be the true elements to be considered in alopecia areata, namely, the constitutional, and especially the neurotic, aspects of the cases. In proportion as I have regarded these in practice, so far have I had success in removing the alopecia areata, both at the time and permanently; whereas purely local treatment has never, in my hands, yielded thoroughly satisfactory results.

I need not dwell long upon the actual methods and details of treatment, for they are such as will readily suggest themselves when a correct knowledge of the true nature of the complaint is obtained and borne in mind.

Patients with alopecia areata should be put in the best possible condition hygienically; for, although they generally seem to be in good health, careful investigation will often show some departure from the normal condition which has more or less bearing on the disease. Thought must be especially directed toward nerve nourishment, and all my cases of late years which have done the best have been treated on this plan. The fats and phosphates should be increased in the dietary, and I always encourage largely the use of fresh butter, cream, fat of meats, etc. Milk is also of great service, if well borne; but, as I have fully explained elsewhere, this does not agree well with adults when taken in connection with other food. I direct it therefore to be taken absolutely alone, in the intervals between meals, say one hour before each meal, and at bedtime, provided this is three or four hours after the evening meal. The idea is, that as milk contains all the elements of nutrition, and is the substance from which the hair was originally grown, it will best aid in its later reproduction and nutrition.

The phosphates are best found in whole wheat, and I encourage the use of whole wheat bread, also crushed wheat with cream, and any other preparation in which the phosphates abound; fish I believe to be beneficial in these cases, and I urge its use once daily.

The medicinal treatment is based on the same principle, and my best results have been obtained under the free and continued administration of strychnia with phosphoric acid. Arsenic is of moderate value, and should be given in alternation with the former. Cod-liver oil is also valuable, especially in patients who cannot or will not take the fats in their dietary; and some of the emulsions, with a large proportion of phosphates, serve the double purpose above indicated.

Locally, the whole treatment is summed up in the single idea of stimulation of the diseased patches. While parasiticides are not actually called for by any local parasite present, experience has shown that many of the remedies used for this purpose are also of benefit in alopecia areata. Bichloride of mercury, in a strength to moderately excite the skin, is frequently the best application; but my preference is for veratria in ointment, of a strength of five to ten or more grains to the ounce. Croton-oil, strong carbolic applications, acetum cantharidis, capsicum, and other stimulating applications may also be used with advantage.

In conclusion, however, I am positive that the best results in the management of this often troublesome affection will be reached when it is looked upon, not as a local affair, but as a manifestation of a constitutional derangement, having its basis in lowered vitality of the nervous system.

4 East Thirty-seventh Street.

Malignant Scarlet Fever is said to be epidemic in parts of Dakota.

THE BABIES' HOSPITAL—A SUMMER'S WORK.[1]

By SARAH J. McNUTT, M.D.,
NEW YORK.

The Babies' Hospital of the city of New York obtained a temporary home and was opened at 161 East Thirty-sixth Street, June 16, 1888.

In August, 1886, Dr. J. Lewis Smith (Archives of Pædiatrics) in reviewing the causes of summer diarrhœa in infants, gave bottle-feeding the most prominent place in his summary. He stated that in the New York Infant Asylum, when bottle-feeding was practised, the deaths kept pace with the admissions; while in the New York Foundling Asylum bottle-fed children were kept by themselves in a room known as the ward of the dying babies. He continued: "Many agents of proprietary foods have been allowed to make trial of their preparations in this ward, but no one has thus far published the result, for it has been thus far one of failure. In all the institutions in and about New York the result has been similar."

It may be added that Dr. Smith's statements but voice the opinions of the profession. Not long ago Dr. Winters made the remark that all wet-nurses' babies die, leaving the inference that bottle-feeding was the essential cause of this overwhelming mortality. The statistics of institutions which depend upon bottle-feeding have been such as to sustain these views; they have been uniformly bad. A recent report from the institution upon Randall's Island stated that but one bottle-fed baby, admitted to the hospital in the last eighteen months, had reached the age of one year.

In the face of such opinions and such results it may not, perhaps, be considered premature if we record a short experience in a hospital which received, not well babies, such as foundlings usually are, but babies which were already desperately sick at the time of admission; and which received them not into a country home, but into an ordinary house, wedged in between other houses in the heart of one of the most crowded parts of the city. Although that experience as yet covers only one summer, it seems to us to demonstrate that bottle-feeding is not necessarily fatal even in a hospital; and that a hospital for sick babies need not be a place for the production of autopsies alone.

From June 16, 1888, to January 1, 1889, admitted, 108: died, 32; discharged, 61; in ward, January 1, 15. Mortality, thirty per cent.

Of the 108 admitted, 51 were females and 57 were males; 79 were in age under one year, 53 were under six months, 34 were under three months, and 15 were under one month. Only 28 were over one year in age. Of the 32 who died, all were under one year; 16 were under six months; 12 were under three months; and 9 were under one month of age. Of the 108, 101 were admitted for gastro-intestinal disorders.

31	of these	were	complicated	with	subacute bronchitis.
5	"	"	"	"	acute "
2	"	"	"	"	chronic "
1	"	"	"	"	empyema.
2	"	"	"	"	pneumonia and pleurisy.
2	"	"	"	"	purulent conjunctivitis.
2	"	"	"	"	adenitis.
6	"	"	"	"	pustular eczema.
1	"	"	"	"	cleft palate.
6	"	"	"	"	rachitis.
1	"	"	"	"	fractured humerus.
10	"	"	"	"	ulceration and prolapse of rectum.
5	"	"	"	"	acute nephritis.
74					

This leaves only 27 uncomplicated gastro-intestinal disorders. Of the 7 cases admitted for other than gastro-intestinal disorders,

2	were	admitted	for	acute rheumatism.
2	"	"	"	hydrocephalus.
1	"	"	"	congenital heart disease.
1	"	"	"	congenital cataract.
1	"	"	"	congenital syphilis.

[1] Read before the Alumnæ Association, Blackwell Medical College, February 18, 1889.

Of the 32 who died, all were cases of gastro-intestinal disease.

3	were complicated	by	acute bronchitis.
2	"	"	" pulmonary tuberculosis
5	"	"	" acute parenchymatous nephritis
2	"	"	" " rheumatism.
1	"	"	" chronic bronchitis.
1	"	"	" congenital syphilis.
18	"	"	" inanition.

Autopsies were obtained in 18 cases. Twenty-two out of the 32 deaths took place during the hot months of July, August, and September. Some of these cases were received in a hopeless condition, but no child under two years was refused admission on account of the character of its illness, except where due to contagious disease.

In considering the details of the work, general hygienic management and selection of food precede in importance the use of drugs.

The hospital is kept scrupulously clean, and the wards are fumigated every two weeks with burning sulphur, averaging 2 pounds for each 1,000 cubic feet. The closet and bath-tub are, after thorough cleansing, daily disinfected with the zinc-salt solution recommended by the Board of Health:

Zinc sulphate	4 oz.
Salt	2 oz.
Water	1 gallon.

Once a week the waste-pipes are flushed with a hot lye solution, one-fourth pound to one gallon. The very ill children were disturbed as little as possible, were moved very carefully, and were kept perfectly clean and dry. All soiled articles were removed at once and placed in the zinc-salt solution. In the summer a number of hammocks were provided for the babies. These were suspended upon the back porch and protected from the sun and wind. There were carriages for those who could not be raised from the horizontal position.

Food.—Since most of the children were received suffering from digestive disorders, and all were dependent for recovery upon the condition of the stomach, most careful attention was given to that organ. The selection of food, the quantity, and intervals of feeding, were studied in each case. In cases received with gastro-intestinal catarrh, where the child was robust, it was first fed upon barley gruel of the consistency of skimmed milk. Where the child was constipated, oatmeal gruel was used. The gruel made from the Crown Wheat Food answered admirably in some cases. Where the child's vitality was low, to these was added the white of an egg beaten to a froth, one-half ounce to one ounce, with each feeding. In very much reduced cases Rudisch's sarcopeptones were useful, one-half drachm to one drachm in two to three ounces of the diluent. Beef peptonoids have been used in the same proportions. Wine-whey, one-half ounce to one ounce in one to four ounces of the gruel; also cream, one-half drachm to one drachm to each feeding, have been used as indicated in the case. Milk has been avoided until the fermentative changes have been overcome. As soon as possible, however, milk has been substituted for these foods, beginning with the proportion of one-sixth. At the end of two to six days, if no curds appeared in the stools and the child was gaining weight, the proportion was increased to one-fifth, and at the end of another week or ten days, to one-fourth, ascending according to the age and digestive ability of the child, always continuing a certain amount of dilution until the child was eight or ten months old.

Sterilized Milk.—Early in the fall, through the kindness of a gentleman who visited the hospital and became interested in the children, milk was obtained directly from a private farm in Westchester County four hours after milking. This has, during the later months, helped greatly to simplify the question of artificial feeding. The milk is obtained in the morning. It is then immediately sterilized in an amount sufficient for the next twenty-four hours, the Soxhlet process being used. When the baby has been removed from the hospital, and the mother has been unable to buy this apparatus, she has been directed to boil the milk in a preserve-jar for an hour, and then to close the jar carefully as though sealing fruit. This has been found a very fair substitute for tenement-house use. In the hospital, however, the details have been attended to with the most scrupulous care. All gruels and other prepared foods also have been kept in small air-tight bottles, and a bottle once opened has not been returned to the ice-box or used for another feeding. As soon as the child has finished nursing, its bottle has been immediately emptied, rinsed, and filled with a solution of the bicarbonate of soda and the nipple washed and placed in cool water.

The Soxhlet apparatus, as sold in this city is, unfortunately, supplied with red rubber stoppers, the color being due to the sulphuret of mercury, which is dissolved by the fat of the milk. Even in poor milk the amount dissolved is considerable, while in milk to which cream has been added it gives a perceptible pink color. Quite early this fact was recognized, and after ineffectual efforts to obtain pure rubber stoppers, cotton-wool was substituted while boiling, inserted as a plug. After removal from the fire, ordinary cork stoppers were inserted, the bottles were inverted so as to stand upon the corks, and when cool enough placed upon the ice. As the milk is kept only for twenty-four hours, this method has been found completely satisfactory.

Where diluted milk was not well borne, the previously sterilized milk was partially or completely pancreatized. The stools have been in all cases carefully watched for curds, the reaction noted, and the stools tested with ether for undigested cream. If curds persisted, the milk was withheld for a time, and the barley gruel or other diluent was given alone, or in combination with the white of egg, wine-whey, or peptones. This treatment was continued for twenty-four to forty-eight hours, and in some cases for from ten days to two weeks.

In one case, that of a baby of nine months, with catarrhal pneumonia and gastro-entero-colitis, only sarcopeptones could be digested for three weeks. In other cases cream would be usually added to each feeding with advantage, one-half to one drachm in amount. Where the requisite quantity of food given every two or three hours could not be retained, one-half drachm to two drachms were given every ten to twenty minutes, or one-half ounce every half-hour. To each child was given also, several times a day, one drachm to two drachms of water, previously boiled and cooled.

Where no food was retained by the stomach, nutritive enemata were given every four hours of one-half ounce of peptonized milk alone, or, combined with the sarcopeptones, one-half drachm to one drachm. To this stimulants were added if necessary. If the rectum had become irritable, an astringent injection was given one to two hours before the enema. This might consist of ten grains of tannin to one half-ounce of water; one-half drachm of the subnitrate of bismuth to one half-ounce of water; or one-fourth grain of nitrate of silver to one-half ounce of water. One to two drops of the deodorized tincture of opium were added to the injection where required. The bowel was flushed with warm water just before the nutritive enema was given. In cases where it was found that milk could not be taken at all, the following artificial foods were tried: Mellin's, Carnrick's, Malted Milk, Horlick's, and Imperial Granum. The results may be briefly summed up as follows:

7	did well	and 4	badly	on Mellin's Food.
1	"	2	"	Imperial Granum.
4	"	3	"	Malted Food.
7	"	7	"	Carnrick's.

Nineteen cases could take pancreatized milk from the beginning; 13 could take it at intervals. Nineteen could take sterilized milk undigested from the beginning; 29 could take it after a time, varying from twenty-four hours to three or four days. Five could take the undi-

gested sterilized milk, but could not take pancreatized milk, while 17 could not at any time take milk. It is apparent that milk has been preferred to the prepared foods in the larger number of cases. A considerable degree of our success with its use has been due, however, undoubtedly, to the extreme care in its selection, preservation, and preparation.

Baths and Massage.—All the children were bathed twice a day quickly, and where the debility was great the bath was followed by an oil rub—cod-liver oil four ounces, alcohol one ounce, being used. The bath in such cases consisted in a quick sponge in water of from 95° to 105° F. The oil inunction was found of special service in cases of dry, wrinkled skin, irritability, and glandular inactivity. The temperature of the bath has been gradually reduced as the child gained in strength, but has at no time been given below 60° F. Where convalescence has been slow, the child has been rubbed briskly with the hand over the loins and back until the skin was red, placed in warm water in the sitting position, and had turned over the shoulders and back a pint of cold salt water and then quickly dried with a thick soft towel. This was repeated daily if the reaction was good. General massage was given in some cases.

Case I.—Clara, aged fifteen months; admitted with pneumonia and pleurisy in November, made a good recovery, but was slow in gaining weight and strength. On admission she weighed fourteen and a half pounds; when resolution was completed she weighed only twelve and a half pounds, and remained very listless and the muscles flabby. December 15th, massage was ordered, followed by cod-liver oil inunctions. The appetite soon improved and the countenance brightened. The child now weighs fourteen and a half pounds; is able to sit in a chair, and attempts to walk.

Case II.—Theresa, aged one year; had been ill all summer with vomiting and diarrhœa. This condition was relieved, but the child remained greatly depressed. The weight was but eleven and a half pounds, and the child would lie in one position all day, apparently unable to move. Faradization and massage were used daily, followed by inunctions of cod-liver oil. Improvement was in every respect marvellous. The appetite increased, gradually the limbs began to be moved, and, after one month of treatment, the child can stand alone, and weighs sixteen and one-fourth pounds.

Case III.—Frances, aged thirteen months; admitted in September with gastro-intestinal catarrh; made a slow convalescence, remaining thin. She could not raise the hand, and would lie listless all day. She weighed but nine pounds. November 27th, massage was commenced, followed by inunctions of cod-liver oil. She now weighs ten pounds, is able to sit up, and moves her arms and legs for the first time since her admission. The treatment is continued.

Case IV.—Ethel, aged six months; was admitted in October, weighing eight and three-fourth pounds; suffered from gastro-intestinal catarrh. This condition improved, and the child ate and slept well, but remained constipated. November 8th, the weight had increased to ten and three-fourth pounds. Massage was commenced, and continued until the child was discharged, December 14th, with normal stools and weighing thirteen and three-fourth pounds.

Case V.—Tom, aged one year; had suffered all summer with gastro-intestinal catarrh. This condition had been controlled, but there had been no gain in weight, which remained at about thirteen pounds. Massage and oil inunctions were commenced in October. The child immediately began to gain in weight, and now weighs seventeen pounds, can stand alone, and forcibly move his limbs.

Flannels merit a separate place in the consideration of the treatment of these children. The entire surface was covered by thick flannels. The chest and abdomen, from the neck to the hips, were in all cases covered by a thick bias band. This was cut from twilled flannel, which adapts itself to the form readily, and was made twelve inches broad by three-fourths of a yard long. This was changed at night for one precisely similar, no article worn during the day remained on at night, and all clothing to be reworn was exposed to the air for several hours. Hot water-bags were used in cases of cold feet, colic, and subnormal temperature.

In acute febrile disorders accompanied by undigested stools, mucus, and fetor, Leaming's mixture of castor-oil was given, one-half to one drachm after each stool, until the character changed; or, if stomach symptoms and acidity of the stools were marked, the aromatic syrup of rhubarb, with bicarbonate of soda, with or without paregoric, as needed, was given in the same way. No one remedy, however, has given such complete satisfaction in obstinate cases, with irritability, wasting, anorexia, indurate inguinal glands, with or without fever, as calomel in small and frequently repeated doses of one-twelfth to one-sixth grain every two hours, with or without bismuth or soda, or both combined, until a change occurred in the character of the stools. It was then interrupted for antiseptics, astringents, or tonics. Frequently the calomel was repeated every four to six days, for two or three weeks, before convalescence was established. Another way of exhibiting this drug has been to give one-thirty-second grain every two hours for twenty-four hours; then one-eighteenth grain every four hours for twenty-four hours; and then one-sixth grain every six hours for twenty-four to forty-eight hours. The following cases, with a non-syphilitic history, were successfully treated in this way:

Case I.—Evelyn, aged six months; admitted with alternate constipation and diarrhœa, complicated with chronic bronchitis. The inguinal glands were enlarged. After the calomel treatment the apathetic look disappeared, the bowels became normal, glands less indurated, food was digested, and on sterilized milk and cod-liver oil the child made a rapid convalescence.

Case II.—Fanny, aged fourteen months; admitted in September with gastro-intestinal catarrh, had improved somewhat, but remained remarkably thin and without muscular power. There were enlarged inguinal and mesenteric glands, and enlarged abdominal superficial veins. At the time the calomel was given the child had a subacute bronchitis and four to ten stools daily; the rectum prolapsed. The stools were at once reduced to one or two daily, and the child gained the first week one-half pound. In the second week she gained two-thirds of a pound, and could sit propped up with pillows in bed. In the third week the digestion began to lag, and the stools were increased in frequency. The calomel was repeated, with a similar improvement. The diminution in the size of the glands was very apparent after the use of the drug.

Case III.—Henrietta, aged nine months; admitted in September with entero-colitis and subacute bronchitis. The temperature varied between 97° and 104° F., the greater part of the time being nearly normal. Treatment by regulation of diet, correctives, antiseptics, and irrigation did not apparently accomplish much, the emaciation became extreme, and the child was unable to move her limbs. She was having loose stools containing mucus and blood when the calomel was given. After three days' exhibition of the calomel it was discontinued; the tincture of nux vomica, one-fourth to one-half a drop, was given in ten to thirty drops of the infusion of chamomile; also cod-liver oil, ten to fifteen drops with one to two drops of the spirits of ether, t.i.d. The child gained two and one-half pounds during the succeeding month.

Case IV.—Mary M——, aged nine months; admitted November 2d with entero-colitis. Antiseptic, astringent, and corrective medication, also irrigation—all did well in turn—but the effect was not permanent. What the child gained one week she lost the following. December 10th, the stools continuing to contain mucus and blood, calomel was given in the doses mentioned, and was followed

by the bitter infusion and the liquid nitrate of iron. Permanent improvement dated from this treatment. The child gained one-half pound the first week.

CASE V.—Louise, aged three months, weight six and one-half pounds; admitted November 3d; gastro-intestinal catarrh. The usual astringents and antiseptics produced but little effect. The stools were one week good and the next week bad. After calomel there was improvement, which persisted until the child left the hospital.

CASE VI.—Frank, aged fifteen months; chronic bronchitis, temperature normal; pulse, 128 to 130, fair; respiration 68 to 72. The physical signs improved, as shown by the examination of the chest, but with little diminution in the frequency of the respiration. Calomel was given in the doses mentioned for four days, and at the end of that time the respiration was 30, and afterward remained low.

Irrigation of the bowel was resorted to where diarrhœa persisted after unloading the stomach and bowels, and particularly where there had been an excessive drain of fluids and thrombosis of the cerebral sinuses were feared. The water, previously boiled, was used cold if the temperature were high, and quite warm where the temperature was low or the vitality depressed. The irrigation was made by means of No. 9 soft rubber catheter, to which a funnel was attached by means of a piece of rubber tubing. The douching was continued until the water returned clear.

Patients previously very fretful would frequently go to sleep during the irrigation, and remain quiet for a number of hours afterward. Frequently the stools would be controlled without medication, but where this was not the case tr. opii, deodorized, one to three drops, with starch, or bismuth, or tannic acid, were injected, according to the indications. The irrigations were given once a day where needed. If there was reason to suspect ulceration of the colon, a high injection of silver, gr. ij., water, ʒ iv. (which was returned through tube immediately), preceded the starch-and-opium injection.

LAVAGE.—A number of cases of gastro-intestinal disorders which did not respond to regulation of the diet, medication, and irrigation of the bowels were treated with lavage. The treatment was applied as a last resort, and not because the cases were such as would show typical results. August 21st there were four of such desperate cases in the ward, with pronounced gastric symptoms. Lavage with tepid salt-water was used once daily, twenty minutes before feeding. A baby's stomach-tube, slightly larger than a No. 9 catheter, with a funnel attached, was used, care being taken not to elevate the funnel more than six inches above the head of the child, who was lying upon the left side upon the nurse's lap. Other cases, admitted later, which did not soon yield to other treatment, were also given the advantage of this method, which was carried out systematically for a month. During this time eighteen cases were treated. Of these twelve died. Of the twelve who died, abundant cause was found in the clinical history and in the lesions which the autopsies disclosed. The prognosis, as has been said, was in all of these cases grave when the treatment was undertaken. Of the remaining six cases, four were discharged cured, one on the eighth day, having had four treatments; one on the fifteenth day, having had eight treatments; one on the seventeenth day, having had three treatments; and one on the eighteenth day, having had two treatments. The other two were improved, but left before their recovery was complete, one on the seventh and one on the twenty-first day.

While this manner of application cannot be considered a fair test of the value of the treatment, it will furnish, perhaps, some incidental information regarding the precautions necessary when babies are subjected to lavage, also perhaps some of the most common results.

1. In these cases the secretion of mucus by the stomach seemed to be controlled. In cases where a large amount had been removed by the first washing, very little was found in the second and third, and later none at all. 2. The child was, as a rule, nauseated for the first time or two, but not during the later applications. 3. The pulse, which was always taken just before the operation, immediately after, and again one hour after, always showed a rise of from ten to twenty-five beats during the operation, and at the same time a diminution in force, but generally would fall during the succeeding hour to the rate which had preceded the operation. Sometimes, however, stimulants were needed. In very delicate children, not infrequently the pulse remained a trifle higher and weaker than before the operation, and if lavage were continued for a number of consecutive days a gradual loss of power and increase in the number of beats were noted. If, however, the treatment was interrupted, the usual frequency would return. This depression could not have been due to fright, as, though the child might be annoyed by the first treatment, later he would lie quietly, sucking or biting the tube and watching the funnel. In several cases the child was not inconvenienced from the first. 4. In one case spasmodic symptoms appeared about three hours after lavage. In this case the child did not take food well, and was fed through the tube while in position.

Lavage would therefore appear to be an advantage in sthenic cases, but since in all cases it is accompanied by a certain amount of shock great care should be exercised. In all cases the treatment should be administered by the physician, and stimulants should be given through the tube if needed.

During December lavage was used in five additional cases of children, one to two months old, where the indigestion was not corrected by regulation of food and drugs. In all five cases the fontanelle was depressed, the pulse very weak, and there was little hope of recovery. Stimulants were given before the operation. In all cases the restlessness was quieted at once, although the pulse increased ten to twenty beats, and was difficult to count. Food was given at the end of one-half hour, and was retained for the first time in days. The improvement continued in one case until the fifth day, when the lavage was repeated. In another case it was repeated upon the sixth day, while two cases convalesced and did not need a repetition after one treatment. In these very young children shock was not more marked than in the child of one year or eighteen months; but, as previously stated, the child should be carefully watched after the operation. Where, however, other methods fail, the little patients should be given the advantages of this method of treat ment.

ANTISEPTICS.—After free evacuation the following antiseptics have been used: Bismuth, resorcin, salol, creolin, pancrobilin, sodii salicylate, and merc. bichloride. Bismuth has been used in almost all cases. Finding upon autopsy that the mucous membrane of the duodenum was, as a rule, so swollen that bile could be scarcely forced from the gall-bladder into the intestine, it seemed a logical idea to supply bile. Pancrobilin has, therefore, been considerably used, and with apparently good result. Resorcin was given in seventeen cases with fair results. In four cases, however, it was found that after continuing the drug several weeks it interfered with the kidneys, and gave rise to violet-colored urine, which upon standing became black. In two of the four cases suppression was induced, lasting eight to ten hours. Creolin in half-drop doses, suggested by Dr. Kinnicut in consultation, was used in twenty-one cases with excellent results. In two cases, however, green urine was voided and suppression supervened, lasting a number of hours. Salicylate of sodium was given, one-half grain every two hours, in several cases of marked acidity of the gastro-intestinal tract and where indicated by acute rheumatism or tonsillitis. The bichloride of mercury, $\frac{1}{100}$ grain, was used in a number of cases with a fair result. Salol was used in four cases in a dose of one-half grain. The results were not satisfactory. In prescribing medicine glycerine has been

used to sweeten it instead of syrup. Paregoric and the deodorized tincture of opium have been used. Morphine, $\frac{1}{14}$ grain dose, was given hypodermically in one case of uræmic convulsions, controlling spasm. Efforts were, however, made to limit the use of this drug and to allay pain by heat. Where colics did not yield to hot poultices or hot bags the nurse was directed to give one dose of "baby mixture." This consisted of one-half grain of sodii bicarb., five drops of spirits of chloroform, ten drops of glycerine, made up with water one drachm. This was added to two teaspoonfuls of hot water, the cup having been previously warmed by dipping into hot water. It was given quickly, and repeated in one-half hour if the pain was not controlled. Where the child was wakeful at night the tincture of hyoscyamus or the compound spirits of lavender was given in two- to five-drop doses in the "baby mixture." For an accumulation of gas in the intestine a quarter to one-half drop of the tincture of capsicum, or the same dose of the tincture of assafœtida, was added to the "baby-mixture," or a drachm of the tincture of assafœtida, diluted with warm water, ℥ iv., was injected into the bowel. As alkalies, chalk or the carbonate or phosphate of soda were generally used. As astringents, bismuth, nitrate of silver, tannin, or krameria. As stimulants, alcohol was usually preferred on account of its purity and lack of taste. Musk was used by suppository in one-grain doses where collapse was threatened. In cases of high temperature, where alcohol was not sufficient, camphor was added. Strophanthus, one-fourth to one-half drop every half-hour, one or two hours, has given most gratifying results, as shown by the following cases:

Case I.—Cecilia, aged fifteen months; entered in November with pneumonia of lower lobe, left side, and pleurisy of both sides. The father had been carrying her around the city all day in a cold storm, trying to find a hospital which would admit her. The mother had been intemperate for several years, and was at the time suffering from a two weeks' debauch. The child was not yet weaned, and was presented with its clothing saturated and in collapse. Temperature, 104.8° F.; respiration, 60; pulse, 140. Tr. digitalis, gt. one, every four hours, and brandy, one-half drachm, every one-half hour, produced but little improvement in the pulse. Nutritive enemata, containing one drachm of brandy, every two hours were added. Four and one-half ounces of brandy were given each twenty-four hours, for three days, the pulse remaining 136 to 148, and compressible, while the temperature had fallen to 99° F. Musk and camphor were then added, but the pulse continued at 148 and intermittent. The child was seen in consultation with Dr. A. H. Smith, who suggested the tincture of strophanthus, one-half drop every two hours. In twelve hours the pulse had fallen to 124, and had become regular and increased in force. The brandy was then diminished to one-half drachm every two hours. Within a week the pulse had fallen to 108, the brandy replaced by bitter infusions, and the strophanthus given t.i.d. The child made a good recovery, resolution occurring upon the thirteenth day.

Case II.—Kate ——, aged four months, suffering from gastro-intestinal catarrh. The movements had become normal, but the vitality remained low. The pulse was 156 and very compressible, although brandy was freely exhibited. November 23d, strophanthus commenced to be given gtt. 1-2 q. 1 h. In twenty-four hours the pulse had fallen to 126, and the quality was fair. November 25th the pulse was 120. The medicine was continued every one hour. November 27th the medicine was given every three hours. From November 28th it was given only three times a day, and was continued in this dose for one week, the pulse remaining at 112, the improvement being permanent.

Case III.—Lottie——, aged three months; gastro-intestinal catarrh. The temperature normal or below; the pulse, 126 to 156, and very poor. The patient had been taking one-half drachm brandy and three drops aromatic ammonia every three hours.

November 24th the pulse was 128 and intermittent. Tincture of strophanthus was ordered, one-half drop every three hours. November 25th, pulse, 118, stronger and intermissions overcome. November 30th, pulse, 108, good; strophanthus given only t.i.d. December 6th, strophanthus stopped as no longer necessary. December 13th, resumed for three days, the pulse having risen to 116, and less strong. It was not necessary to again repeat it.

Case IV.—Fred ——, aged one year; received in October for gastro-intestinal disorder. Temperature below 100° F.; pulse, 120 to 144, quality poor; brandy and ammonia failing to improve the pulse. November 22d strophanthus commenced to be given, one half drop every two hours. At the end of two days the pulse had fallen to 102, with marked improvement in quality, and other stimulants were discontinued. November 5th, the strophanthus was reduced to half drops every four hours. November 27th, to t.i.d. The pulse continued 108, and full, and the child convalesced, without further interruption, on nux vomica and bitter infusions.

Packs have been found more useful than antipyretics by the stomach, in the majority of cases. They were applied of blood-heat, cool, and iced, according to the indications, and covered with thick, dry flannels. The pack from ice-water was of especial value in lung troubles, as it induced a long, deep inspiration. It was changed as soon as hot, and when the temperature was reduced it was allowed to remain on, without changing, twenty-four to forty-eight hours to keep skin active. When packs could not be borne, or were insufficient, quinine was given. Recently phenacetin has been used in doses of one grain every one, two, or four hours. The results have been apparently satisfactory, as shown by the following cases:

Case I.—George B——, aged three months; admitted December 5th, with pneumonia, both bases posteriorly. December 5th, 8 P.M., temperature, 105° F.; pulse, 172; respiration, 92. Poultices were applied to the chest, and phenacetin given, one grain every two hours. At 10.30. P.M., temperature, 102.4° F.; pulse, 160; respiration, 80. December 6th, 1 A.M., temperature, 101.4° F.; pulse, 146; respiration, 68. At 3 A.M., temperature, 100.4° F.; pulse, 132; respiration, 60. The phenacetin was then stopped. There had been no depression of the pulse, and no sweating.

In this same case, December 9th, an exacerbation occurred; temperature, 106° F.; pulse, 160, irregular; respiration, 99. Phenacetin was again given, one grain every two hours. At 7 A.M., temperature, 104° F; pulse, 152, regular; respiration, 72. At 9 A.M., temperature, 102.6° F.; pulse, 132; respiration, 76; and at 11 A.M., temperature, 99.6° F.; pulse, 108; respiration, 48, when the phenacetin was discontinued. The temperature did not again rise above 101°.

Case II.—Lizzie, aged two months; admitted with gastro-entero-colitis. November 29th, temperature, 102.4° F.; pulse, 116; respiration, 58. At 11 A.M. one grain of phenacetin was given. At 2 P.M., temperature, 100.8° F.; pulse, 96; respiration, 44. November 30th, 9 A.M., temperature, 104.8° F.; pulse, 140; respiration, 54; one grain was given. At 10 A.M., temperature, 101.6° F.; pulse, 134; respiration, 48. December 3d, 2.30 A.M. temperature, 102.4° F.; pulse, 140; respiration, 48; one grain was again given. At 4 A.M., temperature, 101.4° F.; pulse, 136; respiration, 44. At 6 A.M., temperature, 100° F.; pulse, 132; respiration, 36.

Case III.—Joseph R——, four months; admitted with subacute bronchitis. December 6th, 11.30 A.M., temperature, 102° F.; pulse, 148; respiration, 50; was given one grain of phenacetin. At 2 P.M., temperature, 100.2° F.; pulse, 130; respiration, 46. At 4 P.M., temperature, 100° F.; pulse, 120; respiration, 40. At 6 P.M., temperature, 98.9° F.; pulse, 118; respiration, 38.

Case IV.—Harry, aged six months; subacute bronchitis and gastro-entero-colitis. December 3d, 6 A.M., temperature, 104° F.; pulse, 168; respiration, 60. Phenacetin

was ordered every two hours. December 23d, 8 A.M., temperaure, 103° F.; pulse, 144; respiration, 52. 11 A.M., temperature, 102.6° F.; pulse, 136; respiration, 46. 2 P.M., temperature, 101.4° F.; pulse, 120; respiration, 50. 4 P.M., temperature, 100.2° F.; pulse, 120; respiration, 44. The medicine was discontinued. December 25th, 5.30 P.M., temperature, 102.6° F.; pulse, 136; respiration, 56; one grain ordered every two hours. At 7 P.M., temperature, 102° F.; pulse, 120; respiration, 54. 9 P.M., temperature, 101° F.; pulse, 118; respiration, 38. Phenacetin discontinued. At 11 P.M., temperature, 100.5° F.; pulse, 108; respiration, 30. The temperature did not again rise above 100°.

Other cases might be cited. At no time in the course of these cases was there any disagreeable after-effect, such as cyanosis, collapse, depression, or sweating. The drug never caused vomiting or eruptions as noted by some experimenters; while its dose being one-half that of antipyrene, with its lack of taste, renders it especially easy of administration. It was given generally in alcohol and water, as it is insoluble in water alone. The pulse and respiration always decreased in proportion with the temperature. To guard against depression, the drug was always discontinued when the temperature had fallen to 101° or 100.5° F. It is probably for this reason that the depressing effects were avoided.

ERGOT.—In cases of threatened heart failure, where the complexion was earthy and the extremities purple, the addition of ergot to other remedies has established a more active general circulation.

CASE I.—Kate W——, aged two months; admitted September 17th with gastro-enteritis. The temperature 99° to 103° F., and the pulse 140, very weak, and the fontanelle depressed, the superficial veins of the scalp distended, and the lips and extremities blue. Stimulants had been freely used, but without effect. Fifteen drops of the fluid extract of ergot were given by rectum every four hours, and continued until September 30th, when the cyanotic condition had been entirely relieved, and the pulse was 116 and of good character. The child was discharged October 9th, cured.

CASE II.—Eliza, aged three months; admitted with gastro-intestinal catarrh. The temperature had been normal or below; pulse 156 to 120. The intestinal trouble was overcome, but the child remained in a cyanotic condition. November 24th, on musk, alcohol, camphor, and strophanthus the pulse remained 156. Ergot was now given in doses of ten drops, with the food, every three hours. November 28th, the pulse was 130 and the extremities were warm. November 30th, the pulse was 120, of good quality. The skin was normal in color and the ergot was stopped. On December 7th, and again on the 21st, the cyanosis returned and the ergot was resumed, each time with an equally good result.

CASE II.—Mamie S——, aged two weeks; admitted with gastro-intestinal catarrh. No rise of temperature; pulse, 140 to 112, and very weak. Alcohol, ammonia, and musk having only a temporary effect, and the cyanosis becoming more marked, ergot was given, ten drops in the food, every two hours. This disturbed the stomach, and one-half drachm was given by rectum every four hours. The pulse improved and the cyanosis rapidly disappeared. Returning later, the ergot was again given by rectum every three hours, with the same result.

A word should be added in regard to the nursing in our hospital. We do not expect a single nurse to take care of a whole wardful of sick babies. The nurses are especially trained in the hospital for this work, with an average of one nurse to every four patients during the day, and one to every eight patients during the night.

Further, we do not try to reduce our expenses to the lowest possible cost, but, relying upon the liberality of our patrons, put the patients' welfare ahead of every other consideration. The average cost of maintenance in the Babies' Hospital is four dollars for each patient per week.

Clinical Department.

CLINICAL REPORT ON SULFONAL.

BY ELON N. CARPENTER, M.D.,

MEDICAL SUPERINTENDENT, LONG ISLAND HOME, AMITYVILLE, L. I.

DURING the month of May, 1888, I was requested to use sulfonal in cases of insomnia accompanying acute and chronic insanity. At that time I had but little knowledge of sulfonal, and was quite reluctant even to give it a trial. Finally, after reading several articles regarding it, I concluded to try it. I did so, beginning in the month of June. In eighty-five per cent. of the cases the result has been very satisfactory. December 15, 1888, my attention was called again to sulfonal by Dr. William H. Flint's article in THE MEDICAL RECORD of that date. I decided to make a thorough test of it in cases of insanity and give my personal attention to the same. I selected several of the most violent and destructive patients in the Home, who were in the habit of receiving narcotics or hypnotics each night. The following is the result:

CASE I.—Woman, married, aged thirty-two, chronic mania of three years' standing. Violent. Been receiving medicine at night for past two years. For past month she has been receiving forty-five grains of chloral hydrate, forty-five minims fluid extract hyoscyamus, which caused her to sleep from 11 P.M. until 5 A.M. Administered forty-five grains of sulfonal at 8.10 P.M., patient asleep at 10.45 P.M.; slept soundly until 5.30 A.M.; very quiet during the day. Second trial: Gave thirty grains at 8.30 P.M.; was asleep in sixty minutes; awoke at 5 A.M. Third trial: 8 P.M., forty-five grains; asleep at 8.45 P.M.; awoke at 6 A.M. Fourth trial: 8 P.M., forty-five grains; asleep in thirty minutes; slept until 7 A.M.

CASE II.—Woman, aged twenty-nine, unmarried. Chronic mania for past seven years. Destructive. Trial first: 8.10 P.M., forty-five grains; went to sleep in two hours; slept well until 5.30 A.M.; quiet during the day; fell asleep at 2.30 P.M.; slept one hour. Second trial: 8.30 P.M., thirty grains; no effect; 2 A.M., gave forty-five grains chloral hydrate; she slept until 6 A.M. Third trial: 8 P.M., forty-five grains; went to sleep at 1 A.M.; more destructive than usual; awoke, 6.10 A.M. Fourth trial: 8 P.M., forty-five grains; 9 P.M., asleep; slept well until 6 A.M.

CASE III.—Woman, unmarried, aged forty-four. Recurrent mania, six years' standing. Very noisy, but not violent or destructive. 8.10 P.M., forty-five grains; went to sleep at 10.40 P.M.; slept until 3 A.M.; dose repeated at 3.30 A.M.; went to sleep at once and slept until noon. Second trial: 9 P.M., thirty grains; 9.30 P.M., sleeping; slept until 6 A.M.; awoke, complained of headache and nausea, with some little vomiting; went to sleep at 7.30 A.M.; slept until noon. Third trial: 8 P.M., thirty grains; asleep at 9 P.M.: awoke at 1 A.M.; asleep at 2.05 A.M.; awoke at 6.30 A.M.; very noisy all day. Fourth trial: 8 P.M., thirty grains; asleep at 8.45 P.M.; awoke at 7 A.M.

CASE IV.—Woman, unmarried, aged thirty-five, melancholia: 8.10 P.M., thirty grains; asleep at 10.40 P.M.; awoke at 5.30 A.M.; at 8.30 P.M. gave twenty-five minims of fluid extract of hyoscyamus; slept from 10 P.M. until 4 A.M. Second trial: 8 P.M., thirty grains; asleep at 9.18 P.M.; awoke at 6.08 A.M. Third trial: 8 P.M., thirty grains; asleep at 8.40 P.M.; slept until 6.35 A.M.

CASE V.—Woman, married, aged fifty-nine, chronic melancholia with cardiac hypertrophy; interstitial nephritis, acute: 8.10 P.M., thirty grains; restless until 2.30 A.M.; dose repeated; asleep in fifteen minutes. The nurse awoke her at 8 A.M.; she refused to eat; immediately went to sleep; slept until noon; ate very little during the day. Second trial: 8 P.M., thirty grains; slept from 9.30 P.M. to 8 A.M. very soundly, when she was awakened; respiration, 16; pulse, 60; temperature, 98° F.; was drowsy all day; medicine discontinued; asleep at 10 P.M.; sleep broken

all night; 8 A.M., respiration, 21; pulse, 80; temperature normal; no medicine at night; 10 P.M., asleep but quite restless; much demented following day.

CASE VI.—Woman, married, aged sixty-one, hysteria: 8.10 P.M., twenty grains; slept two hours during the night; 8 P.M., gave chloral hydrate, twenty-five grains; slept from 9.30 P.M. until 6.30 A.M. Second trial: 8 P.M., thirty grains; asleep at 9.30 P.M.; awoke, 7.12 A.M. Third trial: 8.30 P.M., thirty grains; asleep at 12.05 A.M., awoke, 4.30 A.M.; very drowsy and no appetite for breakfast.

CASE VII.—Woman, married, aged twenty-nine, puerperal mania: 8.10 P.M., thirty grains; asleep at 11; awoke at 4 A.M.; 8 P.M., chloral hydrate, thirty grains; slept from 9.30 P.M. until 6.30 A.M. Second trial: 8 P.M., forty-five grains; 11 P.M., thirty grains; asleep, 11.30; slept until 7 A.M. Third trial: 8 P.M., forty-five grains; asleep at 10 P.M.; awoke the following day at 12.10 P.M.

CASE VIII.—Man, single, aged forty-seven, chronic epilepsy of seventeen years' standing, been taking one hundred and fifty grains chloral hydrate in two doses each night for the past year: 8 P.M., sixty grains; no sleep; 11 P.M., seventy-five grains chloral hydrate and thirty grains sulfonal; went to sleep at 11.15 P.M.; slept until 5.30 A.M.; complained of feeling stupid. Second trial: 8 P.M., seventy-five grains chloral hydrate and sixty grains sulfonal; asleep, 8.55 P.M.; awoke at 6 A.M.; slept very soundly. Third trial: 8 P.M., thirty grains of sulfonal and seventy-five grains chloral hydrate; slept well until 7 A.M.; very drowsy all day. Fourth trial: 8 P.M., fifty grains chloral hydrate and thirty grains sulfonal; asleep at 9.15 P.M.; awoke, 6 A.M.; complained of being drowsy all the morning.

CASE IX.—Man, married, aged twenty-nine, epilepsy: 8 P.M., thirty grains; asleep at 11 P.M., until 5 A.M.; awoke and complained of headache, which lasted three hours. Second trial: 8 P.M., thirty grains; asleep, 10.30 P.M.; awoke, 5.30 A.M., with headache and nausea, which lasted until 10 A.M.; quite stupid; usually bright; discontinued medicine; 10 P.M., asleep; awoke, 5 A.M., quite refreshed. Third trial: 8 P.M., thirty grains; asleep at 10 P.M.; awoke, 6.30 A.M., with headache and nausea; no appetite during day.

CASE X.—Man, unmarried, aged thirty-five, general paresis, violent: 8 P.M., forty-five grains; asleep at 9 P.M.; awoke, 5 A.M. Second trial: 8 P.M., forty-five grains; asleep, at 9 P.M.; awoke at 6 A.M. Third trial: 8 P.M., forty-five grains; asleep, 8.45 P.M.; awoke, 5.30 A.M. Fourth trial: 8 P.M., thirty grains; asleep at 9 P.M.; awoke, 6 A.M.

CASE XI.—Man, single, aged twenty, epileptic: 8 P.M., thirty grains; asleep at 9 P.M.; awoke, 5.25 A.M. Second trial: 8 P.M., thirty grains; asleep at 8.45 P.M.; awoke, 6 A.M. Third trial: 8 P.M., thirty grains; asleep at 9.15 P.M.; awoke at 6.20 A.M. Fourth trial: 8 P.M., thirty grains; asleep at 9 P.M.; awoke at 6 A.M.

CASE XII.—Man, married, aged forty, general paresis: 8 P.M., thirty grains; asleep at 9 P.M.; awoke at 6 A.M.; slight headache. Second trial: 8 P.M., thirty grains; asleep at 9 P.M.; awoke at 6.10 A.M. with violent headache, and complained of thirst. Third trial: 8 P.M., twenty-five grains; asleep at 9 P.M.; awoke, 5.55 A.M.; no headache, feeling well. Fourth trial: 8 P.M., twenty-five grains; asleep, 8.45 P.M.; awoke, 6.15 A.M., much refreshed.

CASE XIII.—Man, single, aged twenty-eight, masturbator: 8 P.M., thirty grains; asleep at 9.10 P.M.; awoke, 6.05 A.M. Second trial: 8 P.M., thirty grains; asleep, 9.10 P.M.; awoke, 6 A.M.; complained of thirst. Third trial: 8 P.M., thirty grains; asleep at 8.50 P.M.; awoke at 6 A.M.; still complained of thirst. Fourth trial: 8 P.M., thirty grains; asleep at 9 P.M.; awoke, 5.30 A.M.

Explanatory reference regarding Cases II., III., IV., VIII., IX., XI., XIII.

CASE II.—One week prior to giving sulfonal, patient was receiving two forty-five-grain doses of chloral hydrate during the night. I desire to say this patient has been given every narcotic and hypnotic I know of, with but little effect, except chloral hydrate; she has had no medicine at all for the past week, sleeps well, and is quiet.

CASE III.—Patient has been in an asylum three times in six years. She is now taking fifteen-grain doses of sulfonal at night, and is more quiet during the day.

CASE IV.—Patient seldom slept over two hours during the night.

CASE VIII.—Was admitted to the Home, July, 1888; he had been in the habit of taking one hundred and fifty grains chloral hydrate at night for several months prior to his admission. I ordered him given seventy-five grains of chloral at 9 P.M., and seventy-five grains at 11 P.M. He generally went to sleep about 11.30. I made an effort to reduce his chloral, but with poor result, after keeping him on the mixed doses of chloral and sulfonal several days. I ordered the sulfonal discontinued, giving him seventy five grains of chloral in two doses at night; he has been sleeping well for the past ten days and made no complaint.

CASE IX.—Patient has been taking bromide of potassium, thirty grains three times a day; twenty grains chloral hydrate at bedtime.

CASE XI.—Epilepsy six years; been taking, for past two months, bromide of potassium, forty grains three times per day; twenty grains of chloral at night; unable to sleep without chloral. Since giving the sulfonal I ordered the chloral discontinued; he has slept well for the past week.

CASE XIII.—Admitted, January, 1888; has had the habit of masturbation for two years; he is quiet during the day, at night talks incessantly, at times maniacal; he now sleeps very well on fifteen grains sulfonal at night.

These histories, I believe, will show what the virtues of sulfonal are in cases of insomnia accompanying mental diseases. Out of several hundred doses of the drug given, I have detected but very little effect on the cutaneous or renal secretions, no constipation, some nausea and vomiting, but this appeared in cases of epilepsy exclusively.

MEDICAL AFFAIRS IN BULGARIA.—A general supervision over medical matters in Bulgaria is exercised by the Minister of the Interior, who is assisted by a council composed of the three head physicians of the Alexander Hospital in Sophar, a veterinary surgeon, and an officer of the State. This council is charged with the direction of sanitary matters, public hygiene, medico-legal questions, etc. There are thirty-four hospitals in the principality, six of which have accommodations for over one hundred patients each, seventeen for fifty patients, and eleven for less than fifty patients each. All the hospitals are under government control, and their expenses are met by the State treasury. The average cost per patient is about twenty cents a day. There are no military hospitals, and the army surgeons are forbidden to retain in the army infirmaries any but those suffering from minor wounds or who have a temperature of less than 99.5° F. All others are sent to the general hospitals. There is no medical school in the country, but there is a sort of training-school where instruction is given in nursing and minor surgery. The State employs one hundred physicians, at salaries ranging from $700 to $900 per annum, twenty of whom are attached to the larger hospitals, the others being district and cantonal physicians. Any graduate of a recognized foreign university who has acquired the right to practise medicine in the country in which he has obtained his degree is admitted to government service or private practice. If a physician have only a diploma, without having acquired the right to practise in the country from which he comes, he is required to submit to an examination in Bulgaria. The average government appropriation for medical service is $400,000 per annum. The general death-rate of the country is about twenty-eight per thousand.—*L'Union Médicale.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 2, 1889.

THE TREATMENT OF RECENT PLEURITIC EFFUSION BY SALINE CATHARTICS.

DIURETICS and cathartics have always been largely employed with a view to the reabsorption of fluids that have accumulated in the various cavities of the body. It is only recently, however, that the use of highly concentrated solution of saline cathartics has been urged for this purpose. In ascites and all dropsical conditions, evidence is not wanting to show that some good may be accomplished in this way.

Dr. P. Blaikie Smith, of the Aberdeen Royal Infirmary, has now extended the method so as to include pleural effusions. He says in the *British Medical Journal*, October 13, 1888, that those whose general practice it is to treat cases of considerable pleuritic effusion by tapping the pleural cavity must confess that, not infrequently, the fluid reaccumulates, and that it occasionally becomes purulent. Recognizing the truth of this clinical observation, he has for some time past discarded operative interference in such cases, relying, for the relief of the effusion, upon the effects produced by saline cathartics, administered in a concentrated form. This class of drugs primarily induces watery evacuations from the bowels, with the necessary result that the blood becomes inspissated and absorption stimulated. Bearing in mind this fact in therapeutics; recollecting, too, that serous exudations have been known to disappear during an attack of cholera (when the blood is to a great extent deprived of its watery element), and that the simple withdrawal of fluids from the diet has been advocated as curative of pleuritic effusion, it seemed reasonable to suppose that if a patient, the subject of this complaint, were starved of fluids and purged by salines, the resulting concentration of the blood would be remedied at the expense of the effusion. In this expectation he was not disappointed, and he gives the records of several cases successfully managed in this way. He uses the magnesium sulphate dissolved in as small a quantity of hot water as possible. The dose employed is two drachms to half an ounce twice a day.

Dr. Smith admits that patients of poor physique, or in whom a phthisical tendency exists, are ill suited for this plan of treatment. So, too, when dyspnœa is an urgent symptom, especially when accompanied by signs of collateral hyperæmia or œdema, the use of the trocar gives more speedy relief than that afforded by free purging. Still he concludes that one meets with many cases where the effusion is large and of recent occurrence, where dyspnœa is not pronounced, and where signs of physical and constitutional debility are absent. These are the cases which, according to him, are peculiarly adapted for treatment by this method.

BIRTH AND DEATH IN MASSACHUSETTS.

THE Forty-sixth Registration Report of Massachusetts, for the year 1887, contains a number of interesting facts bearing on the health, mortality, and social condition of that State. The well-known care which characterizes these reports gives the figures also a wide value to physicians, sanitarians, and economists. We shall present some of the more striking facts given in the report.

The greatest number of marriages takes place in October, November, and, *propter hoc*, the greatest number of births in August. The birth-rate is 26.45 to the 1,000 living, and the death-rate 20.28 per 1,000. The death-rate is greater than it was in the previous twelve years, and greater than it used to be from 1850 to 1862. The birth-rate and marriage-rate have, on the other hand, decreased. These figures do not compare favorably with those of European countries, if we except France and Hungary. Russia is the most prolific of all European countries, having a birth-rate of 49 4 per 1,000 of living population. Hungary, Austria, and Germany follow, while Ireland and France are at the bottom of the list, with Massachusetts close to them in the race. The ratio of male to female births was 105.2 to 100, a ratio that holds good all over the civilized world. The ratio of illegitimate births to the total births for a period of twenty years, in Massachusetts, is 16, figures very favorable to the continence and steady habits of the Massachusetts Yankee. The ratio in Bavaria, for example, is 152 per 1,000 births; in Austria, 134; in England, 53; in Greece, 12. The ratio of illegitimate children born of foreign mothers was 45.9 per cent., showing that the immigrant is a decided factor in the production of illegitimate children.

The death-rate shows that in Massachusetts, as elsewhere, there has been a steady decrease in deaths from constitutional diseases, and increase in deaths from local diseases. There is very little decrease in the deaths from any of the various zymotic diseases, if we except dysentery. The figures for croup, diphtheria, scarlet fever, are just about the same. On the whole, therefore, the statistics here given speak very poorly for the effectiveness or progressive influence of sanitary work.

Of local diseases, consumption and pneumonia have held the leading places as causes of death during the past decade, and evidently the Massachusetts lung is a weak organ. Nervous diseases have increased in frequency, if one may judge by the relatively greater number of deaths from apoplexy and cephalitis.

The death-rate from consumption shows a slight decrease as compared with the ratio for the past twenty-three years. An interesting table is given, showing the death-rate from this disease at different ages, and proving that in 1887, at least, the period of greatest mortality was from 20 to 30, next from 30 to 40, and then from 70 to 80.

The deaths by suicides were 173 in 1887. The suicide ratio in Massachusetts is not, however, a very high one, being 8.6 per 100,000 of population. In England it is

8.1; in France it is 17. There is a remarkable increase in the number of suicides from arsenical poisoning.

We are glad, in conclusion, to note an emphatic tribute made by the editor of the report, Dr. Samuel W. Abbott, to the efficacy of the medical examiner system, as against the older coroner's jury system.

THE MORTALITY OF PNEUMONIA AND TYPHOID FEVER.

In the Annual Report of the United States Marine Hospital Service for 1888, Dr. Charles E. Banks gives us some interesting statistical studies regarding the past and present mortality of pneumonia and typhoid fever.

Reports of the Service since 1872, exclusive of three years, show a total of 3,011 cases and 496 deaths, giving a ratio of sixteen per cent. From 1880 to 1887, the number of cases was 1,649, deaths 311, mortality-rate 18.8 per cent. This would show an increased mortality-rate even in the last decade, an increase which may possibly be attributed to the antipyretic era in therapeutics.

The figures show the highest death-rate (24.1 per cent.) to exist in the Middle Atlantic District, next in the District of the Great Lakes (22.2 per cent.), and in Mississippi, 20.4 per cent., while it is lowest in Ohio (15.4 per cent.).

The average death-rate from typhoid fever in the Pennsylvania Hospital, for a period of twenty years, was 19.5 per cent. The records of the Marine Hospital Service from 1872 show a total of 2,503 cases, with 374 deaths, an average of 14.9 per cent. The greatest number of cases is reported from the Great Lakes, while the Gulf District shows the extraordinarily high mortality-rate of 41.6 per cent. Next to this comes the Mississippi District, with a ratio of 23.6 per cent. The North Atlantic District shows the mortality-rate of 8.9 per cent. (304 cases).

It may be assumed from these statistics that typhoid fever is much more fatal in southern districts than in the north.

In this connection it may be interesting to mention some recent French statistics, given by M. Jubel-Renoy at a meeting of the Société Médicale des Hôpitaux. Doctor Renoy states that, by rigorously treating his cases according to the method of Brand, he has had a mortality of only seven per cent. Adding to his statistics those of MM. Rochard and Josias, a total of 105 cases is given, with a mortality of 4.76 per cent. To all this M. Labbe replies by saying that with a simple expectant treatment his mortality-rate was only five per cent. The cases were all, it is presumed, in private practice.

THE UTILITY OF COLDS.

The question is often asked, how can we prevent "catching colds." The answer is a very simple one: There is no way. Despite the thousands of learned discussions over this matter, the rolling seasons produce just about the same crop of coryzas. Certain individuals adopt some special fad, and for a long time secure immunity; but the mass of people go on sneezing and blowing and snuffling in the same stertorous way. The catching of "colds" is a matter of constitutional vigor. The robust do not catch cold as long as they are robust. But as long as the valetudinarian is with us, we shall always have coryzas, eyelids will redden, noses swell, and pituitary membranes give forth their April showers. But perhaps the coryza has, after all, a conservative function, it warns people of their susceptibility to pathological change; it is a kind of advance-guard against the more serious enemies, bronchitis, pneumonia, and phthisis. In the economy of nature the respiratory organs lack a little in good adjustment to the environment. One-fourth of all deaths comes from the succumbing of these organs to pathological changes. We need to be reminded of the weaknesses of our respiratory mucous membranes. In this emergency the human race was provided with acute rhinitis. Such, at least, is one explanation which teleology gives for the existence of a disorder whose unrecognized benefactions we should be more ready to recognize. As the sinful man needs religion, so the imprudent invalid requires the admonitions of a common rhinitis.

THE REPORT OF THE SURGEON-GENERAL OF THE ARMY.

The Report of the Surgeon-General of the Army for the year 1887–88 is at hand, and is a somewhat larger volume than usual. Over one hundred pages are devoted to a careful analysis of the diseases affecting the army in the military stations. A map is given also, showing the locality and capacity of the military hospitals throughout the United States.

The mean strength of the army for the year was 23,841. Among this number there were 29,727 admissions to the sick report during the year, and an average of 15.5 days lost on account of sickness for each man in the army.

The number of deaths from all causes was 214, or 8.12 per 1,000 of mean strength. The average number of persons constantly non-effective from sickness was 1,010.28. The history of the year shows that epidemic or infectious diseases did not attack the army with any special violence.

We learn that the Army Medical Museum has received 833 additional specimens during the year, making a total of 26,695. The Library has received 10,961 books and pamphlets, making a present total of 130,614. Volume X. of the "Index Catalogue" is now going to press.

The third and final part of the medical volume of "Medical and Surgical History of the War" is being issued.

Surgeon-General Moore says that the service now has 190 medical officers, of whom 15 are on sick-leave. The retirement of some of those now on sick-leave is advised, and an increase of 20 assistant surgeons recommended.

A New Site for the New York Academy of Medicine.—A building site of 75 × 100 feet, with the privilege of adding twenty-five feet, has been secured for the new academy and library, in West Forty-third Street, near Fifth Avenue.

Philadelphia Polyclinic.—Dr. B. Alexander Randall has been elected Professor of Diseases of the Ear, and Dr. Edward P. Davis has been chosen Professor of Obstetrics and Diseases of Children, in the Philadelphia Polyclinic and College for Graduates in Medicine.

News of the Week.

MARGARET ALDEN MILLER, as administratrix of the estate of her husband, Dr. Maurice Norton Miller, has begun proceedings in the Superior Court against Dr. Alfred L. Loomis, to recover $1,000 for services rendered in 1888, and other relief. She declares that her husband wrote the principal part of an essay which Dr. Loomis read at the third annual meeting of American Physicians at Washington, in September, 1888, and revised it for publication. Mrs. Miller has also petitioned Surrogate Ransom for an examination of Dr. Loomis, alleging that she believes certain of her husband's effects are in the possession of the Loomis Laboratory Corporation, at 414 East Twenty-sixth Street.

A GREAT STIR IN MEDICAL and political circles of New Orleans has been caused by the removal of Quarantine Officer Dr. Aby, and the appointment in his place of Dr. Andrews. The State Board of Health, an assemblage of merchants, and another of citizens, have condemned the Governor's action, and appointed committees to wait upon him and request his reconsideration of Dr. Austin's appointment.

THE MORTALITY-RATE IN NEW YORK STATE is a decidedly high one for the past year. The State Board of Health's bulletins show that, during 1888, 104,450 deaths were reported in time for insertion in the bulletin. There were in addition, of delayed records reported, sufficient to bring the mortality for the year up to 110,000. The death-rate for the State from all causes is placed at 19.64 per 1,000 of the population for the year. The proportion of deaths under five years of age, for the past twelve months, was 36.5 per cent.; for 1885 this was 37.3; for 1886, 38; for 1887, 36.3; showing a slight variation year by year, and showing a slight diminution for the past year.

A NOVEL TREATMENT FOR PULMONARY HEMORRHAGE.—At the meeting of the Medical Society of Victoria, on November 14th, Dr. R. A. Stirling narrated a case of profuse bleeding from the apex of the left lung, in which hypodermic injections of ergotin and other commonly used remedial measures had failed to check the hemorrhage, which was sufficiently severe to threaten immediate death by suffocation, but in which the hypodermic injection of $\frac{1}{150}$ grain of atropine at once controlled the bleeding. During twenty-four hours the injections were repeated at intervals of every six hours; then, thinking that the stoppage might have been accidental, the doctor omitted the treatment for twelve hours, with the result of a fresh and severe attack, which was at once controlled by the renewal of the treatment.—*Therapeutic Gazette.*

SALICYLIC ACID.—The question has been raised of late as to the identity of the salicylic acid manufactured by chemical processes with that prepared from the oil of wintergreen and other plants. Serious complaints have been made from widely different sources that the therapeutical effects are not the same in both, and although chemists are prepared to assure us that they are chemically identical, medical men would do well to scan the results obtained in practice from the salts of one and the other origin.—*Medical Press.*

ANNOUNCEMENT OF THE ANNUAL PRIZE OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—A prize, consisting of a gold medal of the value of one hundred dollars, is offered by the Medical Society of the County of New York for the best essay upon any medical or surgical subject submitted to the Prize Essay Committee on or before October 1, 1889, by any member of the Society. The essay must present sufficient original, experimental, or clinical observation to make it a useful contribution to medical knowledge. Essays in competition must be signed by a motto and accompanied by a sealed envelope inscribed with the motto, and containing the name and address of the author. The prize will be awarded at the annual meeting in October, and the name of the successful competitor will then be ascertained by opening the envelope marked with the motto corresponding to that upon the successful essay. All essays in completion must be sent before October 1st, to one of the members of the Committee.

E. H. GRANDIN,
W. G. THOMPSON,
M. ALLEN STARR,
Committee.

THE JENKS PRIZE.—The first triennial prize of two hundred and fifty dollars under the deed of trust of Mrs. William F. Jenks, has been awarded by the Prize Committee of the College of Physicians of Philadelphia, to John Strahan, M.D., M.Ch., M.A.O. (Royal University, Ireland), 247 North Queen Street, Belfast, Ireland, for the best essay on "The Diagnosis and Treatment of Extra-uterine Pregnancy." The writers of the unsuccessful essays can have them returned to any address they may name, by sending it and the motto which distinguished the essay, to the Chairman of the Prize Committee, Ellwood Wilson, M.D., College of Physicians, Philadelphia. The Trustees have made arrangements with Messrs. P. Blakiston, Son & Co., 1012 Walnut Street, Philadelphia, for the publication of the successful essay, which will also appear in the "Transactions of the College" for 1890.

JAMES H. HUTCHINSON,
JOHN ASHHURST, JR.,
JAMES V. INGHAM,
Trustees of the William F. Jenks Prize Fund.

THE FIRST FATAL CASE OF COCAINE POISONING reported in England occurred recently at the University College Hospital. A solution of twenty grains of cocaine in an ounce of water, intended to be used for washing out the bladder, was, by mistake, administered internally. Death took place in about one hour.

MYRTOL is a perfectly clear fluid, and represents that constituent of oil of myrrh which boils at 160° to 170° C. Linderm is the only clinician who has instituted any detailed trials with myrtol. Eichhorst himself was first to apply it in gangrene of the lungs. The results which he obtained were so surprisingly favorable that he has used the drug in numerous cases, and is now convinced that, as a disinfectant of the air-passages, myrtol has not its equal. The drug is best given in gelatine capsules (à .15, prepared in Paris, or by Pohl, of Schönbaum-Danzig). If a capsule is crushed, the peculiar odor clings to the room for a long time, and if a capsule is swallowed, the breath emanates the characteristic odor for many hours, and often for a couple of days. In putrid bronchitis and pneumonic gangrene two to three capsules should be

taken every two hours to deodorize and disinfect the parts. The effect is rapid, and a few capsules suffice to remove the bad odor, and often to produce a permanent improvement. The drug is, however, apt to cause a temporary loss of appetite. Myrtol has also been tried against tuberculosis, but the drug has proved utterly useless against the bacillus tuberculosis.—*Therapeutic Gazette.*

STROPHANTHUS.—Dr. Dujardin-Beaumetz speaks rather favorably of strophanthus, but he has obtained with *extract of oleander* results perfectly identical with those of strophanthus, the only difference being that larger doses of oleander are necessary.

ANTIPYRIN AND SWEET SPIRITS OF NITRE.—There has been much said about the incompatibility and danger, when mixed, of the above drugs. Dr. H. C. Wood (*Therapeutic Gazette*) has shown that when combined they may produce iso-nitroso antipyrin, a compound which is not toxic, but is not antipyretic.

AN ACROMEGALOUS GIANT was recently shown by Virchow before the Berlin Medical Society (*Therapeutic Gazette*). The patient was a very robust and large man, perfectly healthy, and father of six children. His lifting capacity, the reporter says, is truly enormous, for he lifts with ease and pleasure eight hundred pounds. The head of the man shows gigantic proportions, in all directions defying all his hitherto collected anthropological experience. The skull of the giant measures in circumference 65.5 ctm., 2 feet 1¾ inch, in length 22.9 ctm., and in width 16.8 ctm. These figures are far in excess of those taken from other gigantic individuals, such as Murphy and Winkelmeyer, the two well-known giants of Castan's Panopticum (in Berlin), and a Prussian guardsman. While the height of Murphy's body was 7.1, of Winkelmeyer 6.3, and of the guardsman 6.7 times the length of the foot, the comparative index in this instance was only 5.8. His absolute height is 183.8 ctm., or about 6 feet 1 inch.

A NEW METHOD OF ILLUMINATING INTERNAL ORGANS.—The well-known experiment for showing total reflection of light in a jet of water or in a glass rod has been made use of here by Dr. Roth and Professor Reuss in devising a new method of illuminating from outside some cavities of the body, such as the larynx and nose. The instrument used for this purpose is a well-polished (not blackened) glass rod, to one end of which a small electric incandescent glow-lamp, like those used for electric breast-pins, is attached. The light of the lamp is reflected equally through the whole glass rod to its other end, which is placed on the skin of the throat in the case of a laryngoscopical examination being required. Then the interior of the larynx becomes illuminated sufficiently for laryngoscopy. If this luminous glass rod is applied to the sclerotic, the interior of the eyeball can be examined in the same way as by using an ophthalmoscope, the structure of the posterior parts of the vitreous body being very well seen and studied. As the glass rod remains cold, it can be employed in operative surgery to light the natural and artificial cavities.—*The Lancet.*

THE MICROBE OF DIPHTHERIA has been repeatedly discovered and isolated, the best recent work in the bacteriology of the disease having been done by Loeffler, who worked under Koch. That observer did not find a single specific microbe, and we are, therefore, inclined to doubt the results announced by M. Roux, of the Pasteur Institute. He claims, however, in conjunction with M. Versin, to have isolated the specific microbe of diphtheria. The two observers have studied the conditions in which this microbe is developed, and have succeeded in reproducing diphtheritic infection in rabbits, pigeons, fowls, and guinea-pigs. Pushing their experiments further, they have also isolated the poison secreted by the microbe from which are derived all the asphyxic and paralytic symptoms of croup or diphtheria; and it is foreseen that the time is not far distant when prophylaxis by means of inoculation will be established. This discovery will certainly be a great boon, since diphtheria is one of the most cruel maladies which afflict humanity. In the note on this subject by M. Roux, the author further states that all the experiments on animals tend to prove that the microbe of diphtheria develops only on mucous membranes already diseased, and it is probable that this is most frequently the case in man. Hence diphtheria is particularly frequent after an attack of measles and scarlet fever. Hence also, a simple sore throat occurring in these maladies should never be neglected; frequent washings of the mouth and throat of children affected with these two diseases should be practised with solutions of carbolic acid. Even in confirmed diphtheria, carbolic acid seems to be the most efficacious antiseptic.

Obituary.

D. WILLARD BLISS, M.D.,

WASHINGTON, D. C.

DR. D. WILLARD BLISS, one of the physicians who attended President Garfield after he was shot, in July, 1881, died in Washington on February 21st. Dr. Bliss had been in bad health for several months, and two days before was stricken with paralysis, from cerebral hemorrhage. He was born at Auburn, N. Y., in 1825, and was graduated in 1846 by the Cleveland Medical College. He practised in several cities of Michigan.

At the breaking out of the rebellion Dr. Bliss became an army surgeon. In the fall of 1861 he was one of the medical officers selected for a commission by President Lincoln as Division Surgeon, and on the organization of the Army of the Potomac was attached to the staff of General Phil. Kearney, with whose division he served until after the battle of Seven Pines, when he was ordered to Washington and placed in charge of the church hospitals. Subsequently he was assigned to the management of Armory Square Hospital, the largest in Washington during the war. It covered fifty acres, and held at times from 12,000 to 15,000 soldier patients. In September, 1865, he resigned and began private practice in Washington, which he conducted until recently.

Although the treatment of President Garfield by Dr. Bliss was much criticised by the press, due no doubt to an unfortunate error in diagnosis, it must be remembered in all charity that there was a great deal of pressure brought to bear upon the medical staff for positive opinions and direct statements. Under the circumstances, however, a positive diagnosis as to the location of the ball was impossible, and the press gave itself the freest possible license for rebuke, criticism, and abuse. Happily, however, notwithstanding differences of opinion upon many points in the case, the distinguished patient did not suffer as to treatment, and it must in justice be said that Dr. Bliss did his best from every point of view.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNECOLOGY.

Stated Meeting, January 24, 1889.

J. E. JANVRIN, M.D., CHAIRMAN.

ELECTION OF OFFICERS.

DR. JANVRIN was re-elected Chairman, and DR. J. R. GOFFE Secretary, for the ensuing year.

SUBMUCOUS FIBROID OF THE UTERUS.

DR. R. G. WIENER presented a fibroid as large as a goose's egg, which he had removed the Sunday previous from the interior of the uterus of a woman who began having severe hemorrhage the day before. The vagina was tamponed overnight and the operation done the next day. He first attempted its removal by the wire écraseur, but as this broke two different times, he was obliged to complete the operation with the spoon-saw. The uterus contracted firmly, aiding in the expulsion of the tumor and preventing hemorrhage subsequently.

DR. J. R. GOFFE, who had witnessed the operation, remarked that it was surprising how easily the tumor came away after the spoon-saw was resorted to. No nemorrhage attended the operation, and there was none subsequently. The growth had protruded about half-way out of the cervix, and was attached to the anterior wall by a pedicle perhaps an inch and a half in breadth. From his slight experience with such cases he had found no other operation in gynecological practice give equally satisfactory results.

DR. W. GILL WYLIE said that the uterine fibroids belonging to the class of the one presented were easily and safely removable; it was necessary only to enucleate them from the thin capsule by which they were enveloped, twist them off, and usually no difficulty was experienced from hemorrhage or other untoward accident; but in the case of fibroids of a vascular type, which had no capsule, the operation of removal sometimes proved one of the most formidable in surgery. If the growth was deeply situated in the wall the operation might prove more dangerous than hysterectomy. It was not safe to take only a part away, for the remaining portion might suppurate and lead to poisoning.

DR. GOFFE remarked that he knew of one or two cases of the second class of fibroids referred to by Dr. Wylie in which death had followed their removal.

THE CHAIRMAN asked Dr. Wylie what he did with the capsule in cases of pedunculated hard submucous fibroids.

DR. WYLIE replied that it was very thin, and if it could be pulled down easily he tied some of it off, but if hot water was employed it was not likely to cause any trouble if allowed to remain. In reply to Dr. Wiener's question, what objection there was to the use of the wire écraseur, he said it was not very practical, and was liable to take away some of the uterine tissue.

DR. J. R. NILSEN then read a paper, entitled

SOME UNUSUAL COMPLICATIONS IN OPENING PELVIC ABSCESSES THROUGH THE VAGINA, OR BY LAPAROTOMY.

The paper was based on a case taken from his note-book for 1886. The patient had been married nine years, had borne one child, and had one miscarriage six years before he saw her, from which time she dated her trouble. Her symptoms were those of backache, aggravated menstruation with much loss of blood, leucorrhœa, headache, etc. There was a laceration of the perineum, considerable thickening about both broad ligaments, condition of the tubes uncertain. She responded well to treatment by hot douches, tampons, etc. In the fall, not having seen her for three weeks, he received an urgent call, and on his arrival found the abdomen swollen, considerable tympanites, no great tenderness, uterus forced over to the right side by a large mass filling the pelvis and extending back to the sacrum. The mass grew softer, she had chills, and three days after the first visit he discovered a soft spot behind the broad ligament and introduced the aspirator. A small amount of pus was withdrawn which had a bad odor. Several severe chills occurring again, he proceeded to aspirate a tumor in the back part of the pelvis. It had been his custom to draw the urine before aspirating; but as this patient had urinated just before he entered the room, he neglected this precaution. Feeling more fluctuation than the amount of fluid first withdrawn would account for, he drove the aspirator deeper into the tissues and drew off eight ounces of clear fluid, which proved to be urine. He was then reminded that she probably had congenital malposition of the bladder posteriorly, to one side, and back of the uterus.

Three days later his attention was called to a hard swelling over the spine of the pubis, above Poupart's ligament, which he poulticed twelve hours, after which it became softer. Before using the knife, however, he concluded, as he had done in some cases before with perfect result, to aspirate, first pushing up any coils of intestine that might lie over the abscess. The needle had to be pushed in deeply before fluid was reached. Ten ounces of offensive pus were brought away. The patient was turned over in bed and the cavity washed out a number of times. A similar procedure had established a cure in some other cases, but it failed in this one. He then concluded to use the knife, but did not feel at all sure that adhesions had been established to the abdominal wall. The peritoneum was found free and pushed before the tumor. It was incised and stitched to the external wound, and the abscess evacuated of pus. He would have established downward drainage but for the abnormal relation of the parts. The cavity was subsequently washed out through a drainage-tube.

Dr. Nilsen, in commenting upon this case, said that if he had followed the rule of emptying the bladder in pelvic surgery, except when its distention was regulated as a guide, it was very probable he should have pierced both walls, as they lay in contact in the misplaced position. The first small quantity of pus encountered by the needle might have come from a small abscess beneath the bladder, or from a sinús leading down from above. It was not unusual for patients of a nervous or hysterical nature to have retention or incontinence of urine. This one had failed to empty the bladder as she thought she had done.

A few years ago another patient had come to Dr. Nilsen's clinic, in whom the bladder was found entirely to the left of the median line. Within the past year he had seen another similar case. In the one case the malposition was congenital; perhaps it was so in the other. That the bladder could be very much dislocated by mechanical causes alone was shown in the case of a boy who had Hodgkin's disease. He passed urine, but it was found that a catheter of only very small calibre would enter the bladder, and the amount of urine withdrawn was enormous, showing that there had been paralysis of the organ and overflow. The catheter travelled ten inches before urine was reached, and the route was tortuous. At death an autopsy was not permitted.

Dr. Nilsen's results from the use of the aspirator, in cases of pelvic abscess, had been good. The employment of it anteriorly might not be considered at present good surgery; but it was his belief that, in the hands of general practitioners and timid operators, it was safer than the knife, and he had seen it result in permanent cure in a number of cases. He described his method of using the aspirator and washing out the abscess cavity, by which certain difficulties ordinarily met with were overcome.

The discussion on this paper was postponed until after DR. H. J. BOLDT had read a paper on

THE TREATMENT OF SUPPURATIVE ABSCESSES OF THE UTERINE APPENDAGES.

There had been much discussion recently regarding the propriety of operating in cases of disease of the uterine

appendages. It was true many women had been deprived of their appendages without being benefited, and some had found their condition worse than before the operation. But as some men had gone to the extreme in operating, others were going to the opposite extreme of non-interference.

The cases might be divided into three classes: (1) those in which the operation was altogether justifiable; (2) those in which the patient should be watched, kept under ordinary treatment to see what benefit could be derived therefrom, and afterward decide on the question of operation; (3) those cases in which delay was not only not advisable, but was dangerous. The histories of four interesting cases of the latter class were recited.

CASE I.—The patient had been married a number of years, and after a miscarriage had metritis and peritonitis. She was suffering from lumbar pains, cardiac palpitation, dyspnœa, etc. During the last five years she had had a number of attacks of localized peritonitis; there was menorrhagia, and she was suffering from the effects of syphilis contracted five years before of her husband. There was double pyosalpinx and ovaritis. Removal was advised if after a few months relief could not otherwise be obtained. During unusual exercise an attack of pelvic peritonitis was excited, followed by general peritonitis. Examination revealed, where formerly Dr. Boldt could map out definite fulness on each side of the uterus, only diffuse fulness. He concluded that the tubes which had been distended with pus had ruptured. The patient was removed to the hospital, but unfortunately he did not make up his mind to operate until the next day. His diagnosis was proven correct, both tubes had ruptured, which caused general purulent peritonitis. The patient did well the first thirty-six hours, but died of collapse sixty hours after the operation.

CASE II.—Unmarried woman, never pregnant, gave a history of salpingitis previous to her last illness. She was seized suddenly with pain in the lower part of the abdomen, but got along pretty well a few days, when high temperature developed with general peritonitis. There was fulness on the right side of the uterus, where the greatest pain was located, but thorough examination could not be made. He concluded, from the symptoms and past history, that septic peritonitis had developed from rupture of a pyosalpinx. The patient was removed to the hospital and operated upon. His diagnosis was verified. The abdominal cavity was cleansed, some hemorrhage took place, but the patient's condition was low; all bleeding points could not be searched for. A tampon of iodoform gauze was inserted into the pelvic cavity, which acted as hæmostatic and drain. After thirty-six hours it was removed and a hard rubber drainage-tube inserted in its place. The cavity was washed out through this, and all odor disappeared; but on the third day the washings became odorous and continued so until death, on the fifth day. The autopsy revealed diffuse nephritis as the only pathological lesion of consequence. The pelvis was perfectly clean, and nothing was found to account for the putrefactive smell which had existed in the return irrigation.

CASE III.—In this case the patient had marked symptoms, due to double pyosalpinx which had originated in puerperal endometritis. He was subsequently asked to see the patient as soon as possible. Severe pain had started in the right ovarian region during sexual intercourse. There was no evidence of general peritonitis. The former distinct outline of the enlarged right tube had disappeared. Diagnosis of rupture of the tube was made. He operated about two hours after seeing the patient, and found an opening two centimetres in length in the right tube, through which the pus had escaped. The other tube was yet distended. Both were removed. No drainage. The patient made an uninterrupted recovery.

CASE IV.—This patient also had double pyosalpinx of puerperal origin, the tubes being distended about five times their normal size. An operation was advised. July 27, 1887, the patient had an attack of severe pain, starting suddenly in the left ovarian region. Dr. Boldt saw her two hours later, but owing to the great pain and tympanites the diagnosis was not positive. Knowing her previous history, however, he strongly suspected rupture of one or both tubes, and operated about four hours later. One tube was found ruptured, and the other ruptured during the operation. The abdomen was cleansed of pus, and the patient made a good recovery.

In commenting on these cases Dr. Boldt said that in the first one he hesitated too long; the operation should have been done immediately after the diagnosis had been made. He had found no case on record in which recovery had taken place after rupture of a pyosalpinx without operation. He cited two other cases in which no operation was done. In one he diagnosticated double pyosalpinx of puerperal origin and advised an operation; but another physician whom the patient consulted ridiculed the idea, and assured her she would get better without an operation. He was called to see her subsequently, and suspected general peritonitis from rupture of the tubes. She died, and the autopsy showed the right tube ruptured. In the other case there was pyosalpinx commencing some months previously with a criminal abortion. Two other gentlemen saw the patient with him, and, under the circumstances, advised rest and awaiting results. The patient improved somewhat under Brandt's system of massage, yet Dr. Boldt felt that laparotomy should be performed. She afterward developed general peritonitis, but again improved. In spite, however, of her seeming excellent condition his prognosis was guarded, for during the former course of massage the tubes, instead of growing smaller, increased in size. Again she was seized with severe pain and a diagnosis of rupture of the tube was made, but rapid improvement took place. A consultation was held, and the consultants thought it possible, with the patient's improved condition, that the diagnosis of rupture was erroneous. But she soon afterward grew rapidly worse; the next morning it was too late to operate; death resulted. The autopsy showed rupture of the tube and purulent peritonitis.

Dr. Boldt said that at present he would in all cases unhesitatingly advise opening the abdomen and removing tubes which contained pus. If the diagnosis proved erroneous, no harm would result from having opened the abdomen. That diagnosis of pus in the tubes could often be made was proven by his own experience. He laid stress on the fact, however, that the suppurative disease should be in activity, which could be determined by the patient's symptoms. He protested against too prolonged waiting in doubtful cases, for if rupture should take place the chances of recovery from operation were greatly diminished. Having once opened the abdomen for suspected pyosalpinx, and finding hæmato- or hydrosalpinx, the operator should go on and remove the tubes, for they were almost invariably occluded. The patient could not become pregnant, and the symptoms, in patients who would submit to laparotomy, were such as to jeopardize their future happiness unless the condition giving rise to them were removed. One could determine, with more or less certainty, whether the distended tubes were permeable by gentle manipulation. If permeable, the fluid might escape and leave them of diminished size.

In the second case the patient was transferred a considerable distance to a hospital. To-day he would rather operate at her home, although it might be a tenement, and thus avoid delay and injury from the ride. He now considered it a mistake to put in the drainage tube after removal of the tampon and drain composed of iodoform gauze. He thought seriously of aspirating the tubes through the vagina in the last case, but this would be a doubtful procedure; it should not be undertaken unless the walls of the tubes were dense, to prevent escape of pus into the peritoneum, and to determine that fact would be very difficult.

DR. WYLIE thought the writer of the first paper made

a mistake in diagnosticating pelvic abscess as a disease, and not as merely a symptom. He had also spoken of the general practitioner treating these cases; but in Dr. Wylie's opinion no man should undertake to treat them unless a surgeon, and more or less expert. He would say without hesitation that the aspirator had done a great deal more harm than good in pelvic abscess. To speak of curing a case of pelvic abscess, as that condition was understood to-day, was using the term cure in a different sense from what he would employ it. Aspiration only relieved symptoms. He had, for five or six years, been trying to eradicate the former prevailing false impression of pelvic abscess. More than nine cases out of ten were cases of disease of the uterine appendages. Pelvic abscess usually was the result of neglected cases of that kind. If marked symptoms of sepsis had not developed, the only proper course was to open the abdomen. The mortality, when that procedure was resorted to, would not be greater than two per cent. If active sepsis were present, and the pus could be drawn by cannula and trocar inserted posteriorly to the uterus, that should be done, and the cavity be rendered aseptic. This procedure, however, would rarely prove a cure of the cause of the abscess, and subsequently it would be necessary to remove the appendages. But if there were danger in aspirating of wounding the bladder or intestines, the abdomen should be opened, always first in the median line, until the condition present was made perfectly clear.

Dr. Boldt's experience, as appeared from his second paper, went to confirm his views regarding the common origin of pelvic abscess.

Dr. P. F. Mundé thought the last speaker was unconsciously helping to perpetuate the mistake of confounding pelvic abscess and pyosalpinx. By pelvic abscess he understood the existence of an abscess in the cellular tissue of the pelvis, and that such cases did occur he did not doubt in the least. The two conditions differed etiologically, pathologically, and in line of treatment, and should not be spoken of in the same breath. Yet he would admit that many cases of pyosalpinx were formerly spoken of as pelvic abscess. He had already expressed his partial conversion to Dr. Wylie's views on this subject. As to diagnosis, in pelvic abscess and exudation the mass was quite immovable when grasped between the hands, one in the vagina and the other on the abdomen, and the uterus was also ordinarily fixed. But when the abscess was intra-peritoneal or in the tube, it was slightly movable up and down, and the uterus was also somewhat movable. In extra-peritoneal abscess the aspirator should be used and the pus withdrawn; if there was more than an ounce or two he would advise thorough dilatation of the opening and washing out the cavity and after-drainage. Soft rubber drains were difficult to retain even when made with a flange; consequently he had substituted a short hard rubber tube with a flange, with small perforations for the passage of a wire suture and fastening to the vagina; the soft tube could be passed through the shorter one for irrigation.

In three cases of extra-peritoneal abscess which pointed in the abdominal wall, he laid the abscess open above and made through drainage into the vagina, and had the accident happen of rupturing the bladder in passing the drain, not from puncture, but from force required in drawing the drain through a narrow opening. The wound in the bladder closed in each case without difficulty.

Regarding Dr. Boldt's paper, he agreed with him entirely respecting operation. He thought, also, an early operation might have saved the other patients. He would not aspirate, but remove a tube although its walls were thick, or in the condition which had been called pachysalpingitis. The question in Dr. Boldt's class of cases was not one of treatment, but of diagnosis. He knew the abdomen was sometimes opened when it should not, yet we sometimes failed to operate when we should. This was illustrated by a case in which the patient's sufferings led her to insist on an operation in spite of Dr. Mundé's protest that nothing wrong with the appendages could be felt. At the operation, however, pyosalpinx was found, and removal cured the patient.

Dr. A. P. Dudley had aspirated in two cases of pelvic abscess due to falls, and cured the patients. He certainly would not have been justified in opening the abdomen in those cases. Pelvic abscess and pyosalpinx were two quite different conditions, although it was sometimes convenient, when speaking to the patient, to use the term pelvic abscess indiscriminately, or as not indicating the exact location of the disease. Dr. Dudley criticised Dr. Boldt in saying that had the patient been in the hospital he would have operated any way. The wife of the millionaire and of the poor man should be treated alike, and both receive the advantage of an operation when called for.

Dr. Schmidt divided chronic suppurative salpingitis into two forms clinically, the mild and the severe, in the former of which the treatment should be tentative and palliative, while in the latter it should be by operation. Gentle massage toward the uterus might be of benefit in mild cases. He, at least, could not determine by examination whether tubal swelling was due to muscular hypertrophy or formation of new connective tissue in the walls. If due to muscular hypertrophy the case would be more favorable for conservative treatment, since the pus would be more likely to be eliminated by muscular power in the walls.

Dr. Dudley expressed, in the form of a question, doubt whether pyosalpinx could be cured by tampon and massage, owing to the position of the tubes relative to their opening into the uterus, and to adhesions.

Dr. Nilsen expressed appreciation of Dr. Wylie's teachings regarding the distinction between pelvic abscess and disease of the appendages, and the usual origin of the former. He still, however, thought those who had not opportunity to become accustomed to the knife should be warned of the difficulties and dangers they were likely to encounter, and not be led to employ it with careless haste.

Dr. Boldt repeated the fact that he did not operate for tubal disease unless it were in activity. He had never regretted operating but in two cases. Regarding Dr. Dudley's criticism, it should be remembered that hospital patients and those seen in private practice were often surrounded by quite different influences. With hospital patients one had only to gain their consent to carry out the treatment which his judgment told him was best. In private practice the patient's relatives and friends must give consent, consultants must be called in, and thus the operation might be delayed against one's own judgment. Dr. Boldt did not express faith in massage as a curative measure for any case of pyosalpinx, although in a few he had found the tubes permeable.

We do our own Singing.—At the suggestion of a mutual friend we wrote to a certain physician in Texas who had made some reputation as a medical writer, soliciting an occasional contribution to the clinical department of the journal. The doctor quite misunderstood us; and having a good opinion of his powers, suggested that he might be induced—*for a consideration*—to write the *editorials* for us if we wished it!!! We told him a little anecdote, by way of reply, as was the custom of the "late lamented" Abraham Lincoln, as follows: "Once upon a time, the choir of a certain village church was practising over night for services Sunday; a lean specimen of the genus 'tramp,' with a thin, piping voice, poked his head in at the window, and, in a shrill key asked: 'Do you want to hire anybody to sing bass at this church?' The basso, with a voice like distant thunder, rolled his eyes up at him, and in a tone that shook the rafters, said: 'Go-to-hell-Dod-dang-you-I-sing-bass-myself!!!'" That's all we said.—*Daniel's Texas Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. CHRISTOPHER HEATH'S PRESIDENTIAL ADDRESS AT THE CLINICAL SOCIETY—SOME ADVANTAGES OF THE PRE-ANTISEPTIC ERA—HOW TO GUARD AGAINST SHOCK IN SURGICAL OPERATIONS—THE FIRST CASE OF NERVE-GRAFTING IN THIS COUNTRY—LEGAL PROCEEDINGS AGAINST THE MEDICAL COUNCIL—THE MEDICAL DEFENCE UNION—THE DEATH-RATE IN ENGLAND AND WALES—THE SOCIAL POSITION OF ENGLISH DOCTORS AND DENTISTS—DR. GOWERS' LETTSOMIAN LECTURES AT THE MEDICAL SOCIETY OF LONDON—THE PROGNOSIS IN THE VARIOUS SYPHILITIC LESIONS OF THE NERVOUS SYSTEM—SYPHILIS NOT A CURABLE DISEASE—A CAUTION AGAINST TOO PERSISTENT ADMINISTRATION OF IODIDE—CANCER OF THE LUNG AND BRONCHUS—THE DEAD-LOCK AT THE COLLEGE OF SURGEONS—IS APOMORPHINE A SAFE EMETIC GIVEN HYPODERMICALLY?

LONDON, February 2, 1889.

AT the last meeting of the Clinical Society the new President (Mr. Christopher Heath) took the chair for the first time and delivered a short address in which he touched on several surgical subjects of general interest. Referring to the fact that a few years ago the Committee of the Pathological Society appointed a committee to go through the published volumes of the "Transactions," extending over more than thirty years, with the object of ascertaining what cases there were which were incomplete, but in respect to which it was probable the authors could supply additional facts, he suggested that the Clinical Society might undertake a similar inquiry. Mr. Heath put in a plea for the value of clinical, as compared with pathological observation, and protested against the idea that the malignancy or otherwise of a tumor, so far at least as concerned the necessity for its prompt removal, could only be settled by microscopic examination. Clinical experience alone would guide the surgeon as to the cases he ought and ought not to interfere with. Of course it was very satisfactory when the microscope confirmed the diagnosis of a growth made before its removal, and yet how often did we find the after-history belie the prognosis of the microscopists, even when they agreed? Mr. Heath said that if a committee of hospital registrars were to undertake the work of collecting the cases of sarcoma and carcinoma which had passed through their respective hospitals during a period of ten years, following up each case to its termination, we should have a mass of material of the most valuable and reliable description. While ready to give credit to the antiseptic system, he was not sure whether recurrences after operations for cancer were not more rapid in these beautifully healed linear cicatrices than they were in the old days when profuse suppuration probably eliminated any particles of disease that had escaped the knife. He believed there was considerably increased risk to the patient in the exaggerated slowness of modern surgery. For a patient to breathe the vapor of ether or chloroform for over an hour was a serious matter for both heart and lungs, and when to that was added a steady drain of blood going on for an equal time, one could not be surprised at the production of deadly shock. He deprecated elaborate dissections of the living, and urged surgeons to use the left hand a little more. To guard against the shock of large operations on weakly patients he had for some years availed himself of a suggestion made by an American surgeon (whose name he had unfortunately forgotten), viz., to inject into the rectum with a long tube, half an hour before the operation, two ounces of brandy with four of hot water. This acted as a reserve of power which could be absorbed at leisure, and had the advantage over the administration of a stimulant by the mouth of not embarrassing the breathing. The injection could be repeated if necessary, and might be combined with the subcutaneous injection of ether. He also strongly advised the subcutaneous injection of from one-quarter to one-half a grain of morphia, combined with $\frac{1}{120}$ grain of atropine, before the patient left the table, as he believed that not only was pain thus relieved but sickness kept in check.

Mr. Mayo Robson, of Leeds, then showed a girl, aged fourteen, on whom he had successfully performed the operation of nerve-grafting. The patient had suffered for six years from a tumor of the median nerve. This had been removed, leaving a gap in the nerve, and on recovery from the anæsthetic the parts in the hand supplied by the median nerve were found devoid of sensation. Forty-eight hours later, two and one-half inches of the posterior tibial nerve, from a limb just amputated, was grafted into the gap. The ends were attached to the proximal and distal portions of the median nerve with a catgut suture, without tension either on the stitches or the nerve. The wound was well washed out with perchloride of mercury lotion and carefully sutured. Healing occurred by first intention. Thirty-six hours after the nerve had been grafted, sensation had so far returned in the parts supplied by the median that the touch of a pencil could be localized, and day by day sensation became more distinct. Five weeks after the operation the slightest touch could be localized, and though there was diminution in volume of the abductor and flexor brevis pollicis, they were not completely paralyzed. Return of function in the motor portion of the nerve was more gradual than in the sensory. Mr. Bryant asked whether the suture included the whole thickness of the nerve. Mr. Bowlby remarked that the case seemed likely to prove a successful one, but at present it was not entirely so. It was the first recorded case of nerve-grafting in this country, and the first case of primary grafting of a nerve—that was, within forty-eight hours of the injury. Mr. Bland Sutton observed that it did not follow that the piece of nerve grafted had become incorporated with the median nerve; it might act merely as a conductor. In experiments on animals it seemed that anything which acted as a conductor, so to speak, along which the reparative material passed—bits of chicken bone, catgut, etc.—had been found to answer the purpose. Mr. Christopher mentioned the case of a man from whom he had (in the course of an operation for removal of a tumor) accidentally removed a large piece of the external popliteal nerve, with consequent loss of sensation and muscular degeneration in the parts supplied by the nerve; some months afterward he had looked up the patient and found to his surprise that function had been restored. Mr. Mayo Robson, in reply, admitted that the case was not as yet an unqualified success. His answer to Mr. Bryant's inquiry was in the affirmative. He remarked that even if the piece of nerve grafted had not become incorporated with the median nerve, yet, in view of the successful issue, most persons would be inclined to commend the course adopted. Mr. Herbert Allingham then read a case in which he had successfully removed a dislocated internal semilunar cartilage from the knee-joint; and Mr. Bowlby narrated a case of complete dislocation of the elbow-joint, with laceration of the ulnar artery, in which recovery ensued and the joint was freely movable.

The Medical Council have of late displayed unusual activity and severity in dealing with offending members of the profession brought before them. One of the latter (Mr. H. A. Allbutt) whom the Council removed from the Register for "infamous conduct," has gone to the law courts to seek redress and compel the Council to restore his name to the Register. The judges, however, decided against him. The Council are now threatened with another similar action from Mr. Partridge, the advertising dentist, whom they removed from the Dental Register. Perhaps these legal proceedings, and the expense attendant upon them, may somewhat diminish the zeal of the Council in dealing with irregularities. Meanwhile, those

among us who are desirous of putting down unqualified practice may rejoice that the Medical Defence Union has been reconstituted. Mr. Lawson Tait has been selected as president. It is, I think, a matter for regret that of the two honorary secretaries one should be a gentleman reputed to have leanings toward homœopathy.

I must demur somewhat to two statements which have recently appeared in the columns of THE MEDICAL RECORD. One is a question of fact; the other is a matter of opinion, and therefore open to discussion. I will take the former first. In your issue for December 22d a paragraph is quoted from the Paris *Temps*, in which the writer refers to the mortality in England (presumably per thousand persons living) as 31. This is so wide of the fact that I am sure your readers will be glad to have the inaccuracy pointed out to them. In 1887 the death-rate for England and Wales was 18.8, and last year it was only 17.8. It does not reach 31 in our most unsanitary town.

The other point on which I would venture to protest is as to the quotation in your columns (January 5th) from a work entitled, "Good Form in England." There are doctors and doctors in England; but I think the social position of doctors generally has been somewhat underrated in the work you quote from. A medical man who reduces himself to the level of a tradesman by keeping an open surgery and selling drugs across the counter, must, of course, not expect to be received in good society. Even in country districts, however, many a general practitioner may enjoy a very good social position if he has the requisite manners, education, and means. It is scarcely correct to say "dentists have no social position in England." The dental profession has made great strides during the past few years, and in London many a dental surgeon will meet a hospital physician or surgeon on almost an equality. They are not "doctors" because we have no D.D.S., but at least one dentist is an M.D., and uses it. Oculists take the same position as general surgeons, and one (Sir William Bowman) has been made a baronet. Brook Street is only one of many streets where fashionable doctors live. Grosvenor Street is as medical, and Harley, Wimpole, and Welbeck Streets even more so.

LONDON, February 11, 1889.

IN Dr. Gowers' third and concluding Lettsomian lecture he discussed the subject of prognosis. It was not long, he said, since the diagnosis of syphilis as a cause, and the prospect of adequate treatment, were held to warrant an absolutely favorable prognosis in almost every form of disease. This view was still prevalent to some extent. Yet the facts suggested a very different conclusion. The scars on the skin told us unmistakably of imperfect tissue restoration, and that too often the proper elements of a part had perished, and their place was supplied only by cicatricial tissue. The fibrous nodule in the liver meant a loss of liver tissue perhaps many times the area of the scar, and so with other organs. When such a result occurred in the central nervous system, how could perfect restoration of function be expected? In the liver the effect in loss of function might be inappreciable, but in the nervous system each cell and fibre had its special use, and the loss of a few might have effects on function not only appreciable but conspicuous. In a large number of syphilitic lesions of the nervous system complete recovery of function did not, and could not, occur. Yet in many cases the symptoms passed away more or less entirely as the result of treatment. Between entire recovery on the one hand, and entire persistence of the symptoms on the other, we had every degree of partial recovery. Every prognosis must therefore be a matter of individual consideration, just as diagnosis must be. The prognosis depended on the diagnosis. If we realized the nature of the lesion and the fact that the symptoms depended, not on the specific process, but on the simple effects produced in the nerve-tissue, if we pictured to ourselves the changes that had taken place, and considered how long they had existed, we had only to ask ourselves how far it was likely that the mechanism of damage could be removed, and how far the nerve-elements could recover from the damage they had sustained. The lecturer said he would only consider the prognosis of the true specific lesions; those that were doubtfully specific, and those that were not specific in their characters, did not often respond to the special drugs. The two leading principles in prognosis were (1) the dependence of symptoms on the simple processes in the nerve-elements, and not on the specific part of the lesion; (2) the fact that it was the specific process only on which special treatment exerted a direct influence.

Our first conclusion must therefore be that treatment could never influence the symptoms directly. The simple processes that caused the symptoms were scarcely at all amenable to direct treatment, and not at all to the specific treatment. Hence the utmost we could do was to try and remove the specific process, and so allow the nerve-elements to recover if they could. Here, then, were the essential principles that must guide every prognosis. Was the specific process such, and in such a stage, that we could remove it wholly or partially? Was it to be expected that such removal of it as we could effect would be followed by the recovery of the damaged nerve-tissues sufficient in degree and extent to permit the return of function, complete or partial? The first question was as to how far the specific process could be influenced by treatment. The tissue-formation of syphilis was the element that could be influenced with most frequency, with most certainty, and in greatest degree. It could only be made to actually disappear in the early stage, while still soft; it might also disappear when it had caseated, though the removal of the degenerated particles was perhaps not directly due to our treatment. But when fibroid transformation had set in it was doubtful whether our treatment did more than the process. In the process of subacute and chronic inflammation the effect of treatment through the specific element was largely dependent upon the amount of new tissue formed, and upon the stage of development which it had reached. Inflammation caused also a direct damage to the nerve-elements, and this damage was proportioned to the acuteness of the inflammation; in really acute inflammation it was great, and seemed to constitute the chief effective elements of the process. In such acute inflammation we had no true specific features. Our treatment was only to bring the acute inflammatory process to an end, and, if this were effected speedily enough, there was nothing further for the special treatment to do. There was no new tissue to remove, and, when we had arrested the process of inflammation, all we could do was to wait while the nerve-structures recovered; and all we could do in prognosis was to endeavor to form an opinion as to whether they could recover or not. But when the inflammation was chronic or had lasted long, we had to consider also the tissue-formation, the extent to which its removal was possible, the effect it had produced on the nerve-elements, and the degree to which it was possible that they could recover. A secondary question of importance was the relation of the new tissue to the nerve-elements. When fibroid transformation had set in, treatment could not remove it or do more than hasten this cicatricial process. But this process involved contraction of fibres. If the new tissue merely compressed the structures from one side, this contraction was as effective as absorption in relieving the structures from damaging compression. But when the new tissue encircled the nerve-elements the compression was actually increased by the cicatricial contraction. Whenever there was reason to suppose that there was no new tissue which was about to undergo, or had already undergone, the process of fibroid transformation, and that this new tissue was so placed as to surround either the spinal cord, the nerve-roots, or nerve-fibres, our prognosis must be influenced by these considerations. In all inflammations that were not actually acute there was this

new tissue. If the inflammation had lasted for a few weeks before treatment had been effective, we could not assume that the new tissue would be removed. The amount of new tissue would be proportionate to the intensity, extent, and duration of the inflammation, and we had to consider how far the position of the tissue was likely to entail encircling compression. Hence our prognosis must be deferred till we saw what effect treatment had upon the symptoms.

The practical bearing of these facts upon the chief lesions was as follows: Syphilitic growths—gummata—could be removed more completely than any other lesion. When their influence was exerted by simple lateral pressure, the resulting damage to the nerve structure was recovered from in the most complete degree, and hence the prognosis in such cases was good, unless the duration of the damage was very long and its degree very great. When the growth infiltrated, however, the problem became similar to that met with in some inflammations. In all forms of meningitis the prognosis was good except so far as related to the damage to nerves and nerve-roots, which were surrounded by the newly formed tissue, and also the damage to the spinal cord when the dura matter was greatly thickened. In all these cases the effects of the inflammatory damage and of the early compression commonly lessened up to the point when the contraction of the tissues came into operation. But a residuum remained in some cases, and was increased in some of them, though further improvement was not uncommon. After a time some permanent effects might remain. The prognosis of syphilitic neuritis affecting the cranial nerves was chiefly influenced by the duration of the morbid process. If the inflammatory products were in such a stage that they could be removed, the prognosis was good if the damaged nerve-fibres would recover conducting power; but if there was reason to suspect cicatricial transformation of the new formation into fibroid tissue, it was improbable that the degree of improvement would be sufficient to permit severe symptoms to pass away entirely. The same general prognosis was also true of infiltrating growths. In true acute inflammation that was treated early and arrested early, the prognosis was the same as in similar non-specific inflammations. Symptoms of irritation formed a large part of the manifestations of many lesions. The irritation might be that of nerve-fibres, causing pain, or that of motor structures in the cortex of the brain, causing convulsions. The irritation of nerve-fibres was due to inflammation in the first instance, and, secondly, to residual compression. Convulsions from cortical irritation were usually ascribed to the presence of a cicatrix on the surface of the brain; but the facts were equally explicable on the assumption that the "discharges" originated from damaged nerve-cells, and that the discharging tendency was perpetuated by the residual influence of the discharges themselves. The convulsions might persist long after all other symptoms of cortical irritation had passed away, and they were absolutely uninfluenced by anti-syphilitic treatment. The lecturer then discussed the question of the curability of syphilis, and observed that experience seemed to authorize the belief that it was not curable. They might restrain and control its manifestations, but they could never affirm that the virus had been destroyed. He would not enter into the question as to whether or not the later symptoms were due to the direct action of the virus. He gave a caution against persisting too long in the use of iodide. It would probably effect all it could do in six or eight weeks, and if continued longer often appeared to lose its power. It could be resumed if necessary after an interval.

Among the topics brought forward for discussion at the last meeting of the Pathological Society was that of pulmonary carcinoma, in a paper by Dr. Handford. Within a year the author had had, in his own practice, three cases of cancer of the lung, all ending by profuse hæmoptysis. In two of these the tumor was very small, thus rendering the diagnosis difficult. The third case was that of a collier, aged sixty-four, who dated his illness from an injury to the chest received five months previously. He had copious frothy expectoration, occasionally streaked with blood. There were signs of collapse of the upper lobe of the left lung. For three days he brought up from twenty to thirty ounces of blood a day, and finally died from exhaustion. At the post-mortem the upper lobe of the left lung was found collapsed, and containing several nodules of new-growth. The mucous membrane of the trachea was affected, and the growth had spread along the left bronchus, nearly filling it, but without affecting the outside. There were secondary nodules in the liver. Microscopic examination showed all the nodules to be carcinomatous. Dr. Samuel West referred to some similar cases he had recorded, in which the only physical sign was obstruction of one bronchus. There was no hæmoptysis and no secondary growths. Dr. Ormerod related the case of an old man who died from what was thought to be pneumonia, but at the necropsy the bronchi were found encased in new-growth, the mucous membrane being intact.

There are no signs of any healing of the breach at the College of Surgeons between the members and Fellows on the one hand, and the Council of that institution on the other; rather does it continue to widen. The subject is one of interest to a very large number of our profession in this country. The members and Fellows of the College represent, practically, the entire profession in England and Wales. Almost every practitioner takes the M.R.C.S.—whatever other qualifications he may add to it—even if he is intending to practise purely as a consulting physician. Almost the only exceptions are the Scotch and Irish graduates who come and settle among us, and even some of them take it. The final result of the struggle is obvious to all, but its progress is nevertheless watched with interest.

Apomorphine is generally regarded as a safe emetic, even when old discolored solutions have been injected, though, of course, everyone would prefer a freshly made one. Some cases have, however, been recently published which seem to show that it may induce dangerous symptoms when employed hypodermically.

OUR PARIS LETTER.

(From our Own Correspondent.)

THE MICROBE OF CHOLERA—TABES DORSALIS.

PARIS, February 15, 1889.

AT a recent meeting of the Academy of Sciences M. Chauveau read his report on a communication made by Dr. Loewenthal, on researches on the microbe of cholera and its inoculation. M. Chauveau remarked that the presumed agent of cholera, the comma bacillus of Koch, may be cultivated in solid or liquid media. But these cultures are deprived of all pathogenic activity. To arouse this activity one must have recourse to such artifices that the results obtained are suspected of being of little or no value; and this is the principal obstacle to the experimental studies on the prophylaxis and the therapeutics of cholera. M. Chauveau affirms that the only experiments in which proof was furnished of the existence of a choleraic poison, issuing from the proliferation of the choleraic agent, are those of Professor Bouchard, made with the urine of human choleraic subjects introduced directly into the blood-vessels of animals. In conducting his experiments Dr. Loewenthal sought for a chemical agent capable of preventing the bacillary proliferation and the formation of the toxic agent in cultures, in preparations with the pancreas, from which the author was led to conclude that the pancreatic juice, in presence of albuminoid and peptonized matters, determined the toxogenic action of the bacillus. All the other substances combined together, with the exception of the pancreas, insured the development of the bacillus, but no toxic matter whatever was produced. He found that the

salicylate of phenol or salol produced the effect desired. The bacilli ingested, having passed the stomach, arrive in the intestines and there produce, with the aid of the pancreatic juice, the same toxic matter as that of the pancreatic preparation he had made. This matter is reabsorbed, and, according to the quantity and force of resistance of the organism, determines troubles more or less grave, even death. Salol being inoffensive, as Dr. Loewenthal proved on himself, he proposes to administer this substance as a prophylactic remedy, three times a day, at the principal repasts, in doses of two grammes each time. For the treatment of cholera itself, one must, at the manifestations of the first symptoms, have recourse to an initial dose of four grammes, and to doses of one gramme repeated every hour. Twenty grammes of salol may be taken per day. The above researches were conducted at Professor Cornil's laboratory, who reported on them at a recent meeting of the Academy of Medicine. He stated that, "in order to obtain conclusive results, one must be able to give the cholera to animals in a manner as simple and as sure as that we possess for the transmission of charbon, for instance, or of tuberculosis. We are far from this preliminary condition, and this is why the results have not, and cannot have, all the demonstrative force desired. Notwithstanding this, the results of the last experiments of Dr. Loewenthal are always of a nature to furnish one more indication for the trial of salol against cholera in man, and it is this test alone which will permit one to see whether the action of salol, which is certain in the laboratory, and very probable in the animal, will be confirmed or not in man."

Professor Charcot recently delivered a very interesting lecture at the Salpêtrière Asylum, on the treatment of tabes dorsalis, and of some other maladies of the nervous system by suspension. The procedure of the treatment by the suspension of patients suffering from these maladies had been experimented with in the wards of M. Charcot during the last three months of the year 1888. The idea is attributed to Dr. Motchoukowsky, physician to the hospital at Odessa. Notwithstanding a work that this physician had published in 1883, this subject was lost sight of. However, it was reported that twelve ataxic patients had been considerably improved by this means, which had equally re-established the sexual functions in some of the patients that were affected with impotence. This mode of treatment was imported into France by Dr. Raymond, Agrégé of the Faculty of Paris, who had gone to Russia on an official mission. The treatment consists in the suspension of the patient, and leaving him in this state, at first for one or two minutes, then during three or four minutes at the maximum. The duration of the suspension is thus progressive, and the séance is repeated every two days, as it has been found that a more frequent application does not give better results. The apparatus employed for the purpose very much resembles the suspension apparatus of Sayre, and it may be curious here to relate that the Russian doctor got his idea from the following circumstance: Wishing to apply a plaster corset to a tabetic patient affected with scoliosis, with the view of straightening the spine, he suspended the patient from under the arms by means of a Sayre apparatus. A few days after, the patient returned and expressed himself as being very much relieved of his sharp pains. At first the doctor was inclined to attribute the improvement to the application of the corset, but he soon perceived that the diminution of the pains was really due to the suspension. This led him to apply the method to a great many other tabetic patients, nearly all of whom experienced great relief by the treatment. The results thus obtained have been confirmed by the experiments performed at the Salpêtrière. Of fourteen patients who follow the treatment, there are eight in whom surprising results have been obtained; the six others have felt an improvement less marked. One of the effects, not the less curious, of the suspension is the amelioration, or even the disappearance, of impotence. The amelioration is also manifest in other medullary symptoms—the sensation of numbness, and the anæsthesia of the soles of the feet disappear. En revanche, no change in the rotulian reflexes and in the pupillary signs has been noticed in the patients of the Salpêtrière. Results equally considerable have been obtained by Dr. Blocq, who applied the method of treatment to a patient suffering from the malady of Friedreich—the sign of Romberg, the trembling, and the titubation were notably amended. In a patient suffering from sclerosis "en plaques" the employment of the suspension was less happy, as it produced a spasmodic paraplegia, which, however, was transitory.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 15 to February 23, 1889.

LAUDERDALE, J. V., Major and Surgeon. Granted leave of absence for one month, to take effect between March 1st and 15th. Par. 2, S. O. 9, Headquarters Department of Texas, San Antonio, February 15, 1889.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon. By direction of the President will proceed to Fort Leavenworth, Kan., and report in person to Brigadier-General Wesley Merritt, President of the Army Retiring Board of that place, for re-examination by the board, and on the conclusion of his examination will return to this city. Par. 13, S. O. 40, A. G. O., Washington, D. C., February 16, 1889.

PILCHER, JAMES E., Captain and Assistant Surgeon. By direction of the Secretary of War will repair from Fort Wood, New York Harbor, to Philadelphia, Pa., on or about February 23, 1889, for the purpose of giving instruction to the hospital corps of the 1st Brigade National Guards of Pennsylvania. On completion of this duty will return to his proper station. Par. 1, S. O, 41, A. G. O., February 18, 1889.

HARRIS, HENRY S. T., First Lieutenant and Assistant Surgeon. Will proceed to Fort Davis, Tex., so as to arrive there on or before February 25th, and report to commanding officer thereof for temporary duty. Upon return of Surgeon Lauderdale from leave of absence, Assistant Surgeon Harris will return to the Post of San Antonio. Par. 3, S. O. 9, Headquarters Department of Texas, San Antonio, February 15, 1889.

Official List oy Changes in the Medical Corps of the Unitea States Navy for the week ending February 23, 1889.

RIXEY, P. M., Passed Assistant Surgeon. Promoted to Surgeon, November 27, 1888.

BRADILY, GEO. P., Surgeon. Ordered to hold himself in readiness for duty about March 1st to Mohican.

LUNG, GEO. A., Assistant Surgeon. Ordered to hold himself in readiness for duty about March 1st to Mohican.

PERCY, H. T., Passed Assistant Surgeon. Detached from Naval Hospital, Washington, and to the Coast Survey Steamer Patterson.

WHITING, ROBERT, Passed Assistant Surgeon. Detached from Coast Survey Steamer Patterson, and to proceed home and wait orders.

"THE QUICK AND THE DEAD."—We clip the following notice from a contemporary's account of the death of a physician: "We have to lament the death of Dr. S——, of C——, N. J. He died a martyr to duty; forgetful of self and his own sufferings. A loyal, Christian man, and physician. His practice is for sale. Address his widow, Mrs. E. J. S——, C——, N. J."

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 23, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	3
Scarlet fever	314	48
Cerebro-spinal meningitis	1	1
Measles	310	12
Diphtheria	178	63
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

SYPHILIS FROM A BLOW.—A writer in the *British Medical Journal* of November 24, 1888, reports the case of a man who came to him complaining of weakness, malaise, sweating on slight exertion, and not feeling up to his work. Nothing could be found at first to account for this condition, until it was noticed that his hand was bandaged. On examining this, there was found a perfectly circular sore, the size of a threepenny piece, with clean-cut edges, bright red, without discharge, and surrounded by a purple area of very well-marked induration. Suspecting a venereal inoculation, I questioned him closely, but he affirmed most positively that such could not be the case, as he had never "gone in the way" of it. A tonic mixture was ordered and a simple dressing applied to the sore. After a week or so, finding no improvement whatever, but that, on the contrary, he had now an enlarged, hard gland in the axilla, slight sore throat, and a few pimples about the scalp, the writer told him he had undoubtedly got syphilis in some way or another. It was a difficult matter to convince him of this; but, on a close cross-examination, it turned out that he had had a dispute with another man about three or four weeks before, and that this man, who was somewhat intoxicated, had angered his patient so much, that the latter had struck him a blow in the face with his left hand, scratching his knuckle in doing so by contact with the other's teeth. There was no other probable source of infection that could be made out. Large doses of potassium iodide were given, and in a week or so there was marked improvement in all the symptoms. In brief, he was soon well, thus confirming the diagnosis. Being curious to trace the origin of the infection, the author wrote to the surgeon of a distant mining settlement, to which his patient's antagonist had since gone, asking him to keep an eye upon the man, and report. After some weeks he received a reply to the effect that the man had turned up to consult him about well-marked secondary and tertiary symptoms of syphilis, contracted, as he admitted, two years before, and for which he had been under treatment by a medical man, with pills, which, however, he had discontinued, as it was "too much trouble" to go on taking them. This, of course, cleared up the mystery beyond all doubt.

MUSIC IN MEDICINE.—From the time when medical knowledge was first embodied in rules of practice, and probably from a much earlier period, music has held a recognized place in the treatment of disease. Though lauded in connection with the most diverse maladies—for example, with gout and insanity—it has for obvious reasons been chiefly effective in dealing with certain forms of nervous disease. This is only what one would expect from its natural action. It cannot be named along with many drugs in point of apparent accuracy of result. Its place is not in any ordinary catalogue or pharmacopœia. It belongs rather to that group of natural recreative forces which are active in every healthy life, and which operate against the morbid weakness of any part by increasing the vigor of the whole. In so far as it affects the body, it must clearly do so only through the mind and the nervous system. This accounts for its known value in the treatment of mental disorders. Nor can its obscurer action in different physical states be otherwise explained. By acting as a refreshing mental stimulant and restorative it braces the depressed nervous tone, and indirectly that of the other tissues. Thus there is something to be said for the old custom of exorcising pestilences by the sounds of music. Calmed and inspired by harmony, the tonic energies of will and nerve combine to oppose a wholesome bodily tone to the invading scourge, and to prevent that tissue laxity which has often provided the nidus of disease. A similar process is relied on by those who turn to music, among other diversions, for some relief from the pain of atonic neuralgia. In no class of diseases, however, are we likely to derive so much benefit from the use of so pleasant a remedy as in those affecting the mind itself. In melancholia and allied states of depression its value is generally admitted in our own day. Ancient practitioners were also cognizant of its usefulness in this respect. We must all have felt how suitable is its infinite variety and facility of expression to the changing moods of the sane, and it is, therefore, the less difficult to understand how straying minds are pleased and settled by its charm. Certain it is that its beneficial effect is in this case considerable, and our readers, though possibly unable to acquire a knowledge of the art, should at least possess, and if needful assert in practice, a sense of its therapeutic value.—*The Lancet.*

JOHN ABERNETHY.—In the "Life of Sir Robert Christison, Bart.," is the following sketch of Abernethy, noted down when Christison was a student at St. Bartholomew's Hospital: "Abernethy, a very little man, but in figure and countenance uncommonly handsome, had not strength enough to become a great operator. The diagnosis and constitutional treatment of surgical diseases were his favorite field of practice, and in these branches of consulting practice he was at this time *facile princeps* among London surgeons. He was an early cultivator of what is now aptly called 'conservative surgery.' But I do not remember that term as in use at the period in question; and the surgical tendency was to fly too precipitately to the knife and saw. That never was Abernethy's fault. He was a good operator when driven to operate, but he disliked it. Cullen, who was his anatomical assistant, told me he had seen him in his retiring-room, after a severe operation, with the big tears in his eyes, lamenting the possible failure of what he had just been compelled to do by dire necessity and surgical rule. His *ratio medendi* was very simple. In all surgical diseases the digestive organs are apt to get out of order—the stomach and the bowels and the liver—but the liver at the root of all. Without sound digestion there cannot be healthy nutrition, or, without that, vigorous surgical reparation. Therefore the liver must be stimulated by alternate doses of calomel and blue pill, the stomach by some bitter infusion, and the bowels by a gentle saline aperient. This treatment, combined with a rigorous dietary, was found to suit excellently many London dyspeptics who had no surgical complaints; and, consequently, Abernethy's consulting-room soon became that of a physician much more than of a surgeon."—*British Medical Journal*, December 1, 1888.

LEPROSY IN RUSSIA.—Leprosy seems to be becoming more frequent in Russia, several distinct foci of infection existing in different parts of the Empire. Between 1877 and 1888, forty-nine cases of leprosy were treated in the hospitals at St. Petersburg, half the patients being natives of the city. Of the remainder, some came from the infected districts in the Baltic provinces, Kars, and Astrakan, but others were from Kowno, Vitebsk, and Twer, districts which have hitherto been free from the malady.—*Medical Press.*

ACUTE PANCREATITIS.

A CONSIDERATION OF PANCREATIC HEMORRHAGE, HEMORRHAGIC, SUPPURATIVE, AND GANGRENOUS PANCREATITIS, AND OF DISSEMINATED FAT-NECROSIS.*

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Continued from page 231.)

PART II.—*Continued.*

GANGRENOUS PANCREATITIS.—But the subject of acute pancreatitis deserves attention from another event, viz., its possible termination in gangrene.

The earlier medical writings contain occasional references to gangrene of the pancreas, but the evidence presented is so slightly objective as to make them of but little value for present needs.

Grisellius,[78] for instance, has been generally considered to have first called attention to this matter.

His patient, a man forty-two years of age, suffered from frequent colic, which was easily relieved. He was suddenly, without cause, seized with a chill and severe colic, and died quietly in the course of eighteen or nineteen hours. The post-mortem examination showed an extreme quantity of abdominal fat. The pancreas was found sphacelated, in a large mass of fat. "In whose absence nature had supplied another like round mass, on the right toward the liver and attached to the sphacelated part. Veins ran through the middle, like Wirsungian ducts, but without order. This sphacelated pancreas distributed a like contagion, penetrating not only adjacent parts, but even the diaphragm, consuming the left lobe of the lung as in phthisis."

The liver is said to have resembled grumous blood, in color and in substance. There were several calculi in the gall-bladder.

"Other membranes were adherent at the bottom of the gall-bladder and held another stone larger than all."

Although the evidence does not permit an exact diagnosis to be made it would seem as if the sufferings and death of this individual were rather attributable to biliary calculi than to pancreatic disease. The penetration of the diaphragm and the consumption of the left lung suggest that post-mortem softening of the stomach may have aided in producing the described appearances. The clinical history, brief as it is, affords quite a different picture from that to be presented as connected with pancreatic gangrene.

Bonetus[79] credits Barbette with stating that in a case of obstinate vomiting the pancreas was found wholly putrid, rather sphacelated. Again,[80] he refers to the statement of Verzaschka that Glaserus found a semi-putrid pancreas in a case of dropsy.

Bonetus himself[81] records a case of dropsy in a boy in whom the pancreas is stated to have been semi-putrid.

In Lieutaud[82] there is extracted the case of a woman with obstinate vomiting, severe renal symptoms, and pubic pain, in which the pancreas was semi-putrid, almost destroyed.

Also[83] that of a girl with swollen abdomen, hypogastric pain, purulent urine, and diarrhœa. The omentum and a large part of the mesentery were rotten. The liver filled almost the entire abdominal cavity. The pancreas was putrid and the whole left kidney purulent.

Again,[84] in an infant, with dropsy, there was found a putrid omentum and pancreas. He reports[85] that Helvigius found a sphacelated pancreas, omentum and mesentery, also a shrivelled and putrescent liver, with a gall-bladder containing more than a hundred calculi, in a man sixty years of age, who was seized with gastric pain, obstruction of the liver, and dyspnœa; there was black jaundice and œdema of the legs.

He also[86] refers to a case of extreme dilatation of the bile-duct, where the head of the pancreas was swollen, dense, scirrhous, and pressed upon the opening of the cystic duct. The left portion of the pancreas was putrid. Finally, he credits[87] Bonetus with reporting a case of oft-recurring, obstinate tertian fever, in which the pancreas and mesentery were found somewhat corrupted and sanious.

Schmidtmann[88] speaks of finding induration of the pancreas with appearances of inflammation and beginning gangrene in a case of chronic suppurative nephritis with destruction of the bladder.

The case reported by Portal[89] is perhaps the first which demands recognition as illustrating the relation of pancreatic gangrene to hemorrhagic pancreatitis. He writes as follows:

"Gangrene of the pancreas is the frequent result of inflammation. I have found it in several corpses, and especially in that of a merchant of St. Denis Street, who, during a period of more than two years, suffered from severe attacks of colic. They were deep-seated, below the navel, and were often preceded or followed by nausea or vomiting. There was neither swelling nor induration of the lower abdomen; no dryness of the tongue nor thirst. He became much emaciated, the pains increased, the pulse quickened, the heat of the skin became acrid and very strong. The slightest touch of the lower abdomen became very painful. The urine was scanty and red. This state lasted some twenty days, when the patient died unexpectedly. I was present at the autopsy.

"The pancreas was violet-red and soft, a black moisture escaped from its surface, it was almost wholly gangrenous. The stomach and the duodenum appeared inflamed in places."

Although the above case is probably one of the disease now under consideration, the lack of detail in the clinical statement and account of the anatomical appearances makes its value rather historical than useful in determining the relations of the hemorrhage to the gangrenous affections of the pancreas.

Gendrin[90] reports a case which is likely to belong to the series, but which is deprived of a considerable part of its possible value by the lack of sufficient details, clinical as well as anatomical. He states: "We have seen a vast cavity in the region of the pancreas communicating with

---

the jejunum, which was perforated an inch from its origin. The pancreatic tissue was lost in a dense, friable, reddish mass which formed the wall of the cavity, which was filled with a grayish, very fetid pus. The surrounding cellular tissue and the intestinal walls united in forming this suppurating tumor."

The following table of fifteen cases of pancreatic gangrene represent all, with the above possible exceptions, I have been able to collect. Twelve of them have been observed in the past eight years, five of them have occurred in Boston or its vicinity, and three of them are now published for the first time.

The records of the Boston City Hospital give the following details concerning Case LXVI.: The patient, married, forty years of age, with abundant fat-tissue, strained herself two years before her death, while lifting a heavy tub. There were immediate umbilical pain and swelling, but she was not compelled to give up work.

Fifteen Cases of Gangrenous Pancreatitis.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
LVI.....	Haller and Klob: Zeitschr. d. k.k. Ges. d. Aerzte zu Wien., 1859, xv., 577.	M.	63	Always well.....	For 16 days gastric disturbance, vomiting. Now pale, cachectic, thin; yellow, bitter vomit. Epigastrium somewhat distended, tense, tympanitic, sensitive. Abdomen elsewhere moderately swollen. In the evening repeated nausea, vomiting, great prostration, collapse, violent epigastric pain, thence extending over whole abdomen. Traces of blood in vomit. No albuminuria. Death, after rapid collapse, on the 18th day.	The pancreas a thin, flabby, friable, grayish band soaked in fluid. It lay in an ichorous cavity, bounded by the posterior wall of the stomach, spine, spleen, and duodenum, and communicating with the stomach by three openings in its posterior wall. The pancreas was united in front by a few shreds to the omental bursa. Its cells were either disintegrated, or swollen, or opaque. Certain lobules were separated from each other, in part collapsed, with intervening molecules and fat-drops. Pus-cells were present. Splenic vein obstructed by a dark-red thrombus extending to the portal vein.
LVII.....	Trafoyer, 1862: v. Chiari, Wiener Med. Woch., 1880, xxx., 139, 164.	M.	52	Digestive disturbances for 2 months, with decided emaciation.	Sudden, severe colic. After several days a diagnosis of gall-stones by Oppolzer. The attacks were repeated for 3 or 4 weeks, when 18 gall-stones were discharged. Three days later another intense attack, with vomiting; prognosis grave. On the following day a slough discharged from the bowels. Recovery in 3 weeks, and the patient well 17 years later.	Rokitansky examined the slough and recognized it as the sequestrated pancreas.
LVIII.....	Chiari: Wiener Med. Woch., 1876, xxvi., 291.	F.	54	Corpulent, alcoholic. For several years gastric pains and occasional vomiting after meals. Irregular defecation. Stools often black. A few attacks of jaundice.	Violent pains in region of stomach. Slight jaundice and fever. Swollen abdomen, painful epigastrium, nothing abnormal on palpation or percussion. Bedsore in the course of three weeks. Acute parotitis in the 4th week. In the last weeks failing appetite, increasing debility. Death after a short agony, the illness lasting 7 weeks.	Pancreas cylindrical, brownish-black, shreddy, and friable. It lay in the omental cavity, which formed a spacious pus-cavity, the walls densely fibrous with purulent infiltrations of the innermost layers. The liquid contents an offensive black fluid. A round ulcer of the stomach opened into the cavity; there was also a second opening between the two, and five openings into the jejunum. There was a thrombus in the splenic vein, and necrosis of fat-tissue.
LIX.....	Chiari: Wiener Med. Woch., 1880, xxx., 142.	M.	38	Biliary colic a year ago...	Slight, nocturnal, abdominal pain for 10 days, not interfering with occupation. It then became more severe with sensation of twisting in left gastric region. On the 14th day suddenly awoke with persistent vomiting, followed by a dejection. Violent, gastric colic. Soon anxiety, collapse, the epigastrium swollen, tense, sensitive. For a few days signs of intestinal obstruction, the abdomen swollen, the epigastrium sensitive. No fever. After repeated enemata an offensive stool and improvement. At the end of a fortnight a sudden febrile attack, lasting 3 days, with symptoms of stenosis. After a fortnight a slough was discharged from the bowels. Recovery in five weeks, the entire illness lasting some 12 weeks.	The slough proved to be the larger part of a gangrenous pancreas.
LX.....	Chiari: Loc. cit., 139..	F.	46	Strongly built, abundant fat-tissue; often suffered from cramps of the stomach.	Severe abdominal pains for some days, frequent vomit. Signs of a general peritonitis. Slight jaundice. After a chill, copious, black, offensive vomit, which continued till death. Duration of disease some three weeks.	Pancreas dark-brown, friable, lying, attached only by a few rotten, fibrous threads, in the omental cavity. The latter contained also abundant ichorous, bloody fluid, and communicated with the duodenum and transverse meso-colon. Purulent infiltrations of the mesentery. Necrosis of fat-tissue. Numerous calculi in the gall-bladder. General peritonitis. The microscope showed merely remains of the pancreatic acini, but no evidence of hemorrhage.
LXI.....	Israel: Virchow's Arch., 1881, lxxxiii., 184.	F.	27	Typical case of diabetes. A year in the hospital, under treatment.	No particulars given.....	Head of the pancreas, not abnormal, formed the right pole of an ovoid cyst, the wall of which arises immediately from the thickened and fibrous capsule, which is intimately connected with the posterior wall of the stomach and with a small part of the colon. The contents are 300 grammes of opaque fluid surrounding the tail of the pancreas, the tip floating free. The pancreas, thus situated, is flabby, macerated, and impregnated with large hæmatoidin crystals and acicular, orange crystals.
LXII.....	Whitney: Boston Med. and Surg. Jour., 1881, cv., 593.	F.	Adult.	Well till within four months. In this time has had discomfort at the pit of the stomach, and debility, but is able to be about.	Sudden, severe, epigastric pain, with vomiting of a copious, dark-green, viscid fluid. Frequent stools resembling the vomit. Patient sleepless, temperature normal. Death in 5 days.	Pancreas large, firmly adherent to adjacent parts, which were infiltrated with a discolored purulent fluid. The entire gland transformed into a dark, slate-colored, stinking mass, to within 3 ctm. of its attachment to the intestine, where it was sharply defined from the remaining more normal portion. Splenic vein contained a soft, dark thrombus, where it was in contact with the pancreas.
LXIII.....	Rosenbach: Cblatt. f. Chirurgie, 1882, ix., Beil., 66.	F.	57	....	Eight weeks ago, violent pains, without obvious cause, constipation, speedy improvement; 3 weeks ago, constipation again; for 3 days no dejection, now, frequent green vomit, great prostration, marked swelling of left half of abdomen. Behind and below the dilated stomach a fluctuating tumor, immovable, size of a child's head. Laparotomy. Death in collapse after 6 hours.	Pancreas necrotic, from which arose the suspected cyst, which was an abscess between the stomach and small omentum. The contents were an opaque, stinking fluid. There was fecal accumulation from pressure of the cyst upon the upper part of the small intestines, which were adherent to it.

Fifteen Cases of Gangrenous Pancreatitis—Continued.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
LXIV.....	Balser: Virchow's Arch., 1882, xc., 523.	F.	32	Strong, abundant fat-tissue.	Four weeks ago, sudden vomit, at first slimy, then bloody and greenish. Soon violent pains in the loins and back, fever, headache. Scanty, high-colored urine. Abdomen then began to swell. Now no fever, irregular pulse, clear intelligence, dyspnœa, abdominal pain, debility, abundant stools, albuminuria. For a few days temperature from 100° F. to 102° F., rarely normal and subnormal. Great abdominal distention, flanks dull. Five days later sudden death, preceded by increased dyspnœa.	Pancreas, often appearing as if macerated, lay free, with the exception of its duodenal attachment, in a cavity holding about a litre, which was exposed by separating the fibrous and fibrinous adhesions of the root of the mesentery to the transverse mesocolon. It lay on both sides of the spine, extending to the pelvis, behind the cæcum and descending colon, and, in places, separated the muscles, which were covered with shreds. The contents were a greasy, grayish-yellow detritus, mixed with larger fragments, some nearly as large as a hen's egg. These appeared to have been shelled out of cavities the walls of which were in part of an iron-rust color, in part dark brown, in part infiltrated with blood. The wall surrounding this necrosed fat was opaque, grayish-yellow or yellowish-white, narrow, and sharply defined, without purulent infiltration. The mesentery contained numerous large and small opaque-white patches, with, here and there, rust-colored edges. These had a centre of necrotic fat-tissue. There was recent pleurisy, a fatty heart, thrombosis of the left femoral vein, and embolism of the pulmonary artery.
LXV.....	Prince and Gannett: Boston Med. and Surg. Jour., 1882, cvii., 28.	M.	22	Strong, abundant fat-tissue. A week ago, immediately after turning a handspring, felt a sharp pain in the lower abdomen.	In the night, sudden, severe cramp of stomach, vomiting, chills, and sweating. A few hours later, collapsed, anxious, restless. Severe abdominal cramps, circumscribed tenderness near navel. Temperature normal. On the following day fever and diarrhœa. After temporary improvement, lasting a week, there was persistent diarrhœa, pains, and tenderness of the navel, slight fever and considerable tympany just before death, on the 15th day.	Site of the pancreas occupied by a black, shreddy, sloughy, soft, gangrenous mass; these characteristics most marked in the central region of the organ. The head and tail were represented by a central portion of a black, sloughy mass in which no trace of gland-structure was to be made out, which was incapsulated by the external portion. On raising transverse colon a ragged, blackish mass appeared from a rent, in which flowed a large quantity of thin, chocolate-colored fluid, also two or three soft clots, size of an egg. No cardiac source of embolism. Acute peritonitis.
LXVI.....	Homans and Gannett: Boston City Hospital, MS. Records, 1883, v.	F.	40	Umbilical hernia for two years. Irreducible for two weeks, with pain and swelling. Abundant fat-tissue.	On the day after entering hospital, for treatment of hernia, vomited breakfast, severe paroxysms of colic, small, flickering pulse. Nausea and bilious vomiting persisted on the next day, the face became anxious and pinched, the pulse 100, at times indistinguishable, the temperature normal. The pulse became 140, T., 100.8° F., and she became pale, comatose, and gasping, and died on the 4th day.	Hemorrhagic infiltration, and gangrene of the pancreas. Circumscribed peritonitis, gangrenous phrenitis. Acute pleurisy and pericarditis. Thrombosis of the splenic vein.
LXVII.....	Whittier and Fitz: Mass. Genl. Hospital, MS. Records, 1884., v.	M.	49	In past three years, three attacks of jaundice, bilious vomit, severe pains and abdominal tenderness, most marked near xiphoid cartilage.	After dinner burning in stomach, nausea, much abdominal pain. On the following day jaundice, bilious vomiting. The latter persisted for several days, with frequent belching and loose dejections. The abdomen became resonant except in the right flank, generally tender; temperature on the 8th day, 100.8° F. Pulse and respiration rapid. On the tenth day he fell to the floor while trying to leave the bed, and soon died comatose.	Hemorrhagic infiltration necrosis, and sequestration of the pancreas, and multiple, disseminated necrosis of the subperitoneal fat-tissue.
LXVIII....	Mader: Ber. d. k.k. Krankenanst. Rud-Stift in Wien, 1884.	M.	42	For four years repeated attacks of vomiting, without colic, followed by jaundice lasting four or five days.	During first 5 days paroxysms of abdominal pain, swelling of abdomen, vomiting, jaundice, 2 to 3 daily chills, fever: on the 6th day, T., 100.4° F. Some green vomit. Pulse hardly quickened, no albuminuria. Abdomen inordinately distended and resistant, very sensitive, dense, and dull in left upper quadrant. Sudden collapse on the 9th day. Death on the 13th day.	Tail and part of the body of the pancreas very soft, gray, discolored, infiltrated with a thin, ichorous fluid; the peripancreatic tissue partly purulent, partly ichorous. Spleen greatly enlarged, soft; splenic vein contains a soft, partly puriform thrombus, extending to portal vein. Acute lepto-meningitis.
LXIX.....	Gerhardi: Virchow's Arch., 1886, cvi., 310.	M.	36	Powerful frame, abundant fat. In habit of drinking. From early youth attacks of abdominal pain, without constipation. A year ago the attacks became more frequent.	After a hard day's work intense pain in mid-abdomen. In the course of three days no dejection. T., 100.4° F. Slight jaundice then appeared. There was a feeling of abdominal tension, although the abdomen was tympanitic and not remarkably distended. The nausea became lessened, the jaundice increased, the abdomen more distended, there was no excess of indican in the urine. On the 7th day the abdomen tended to retract except in the left upper part, where it was very sensitive. Laparotomy. The abdominal pain remained severe after the operation; there was no stool; and death, preceded by collapse, took place on the tenth day.	Pancreas dense, nodular, with hemorrhagic coating, acini dull, yellowish-gray. Dry, hemorrhagic masses with yellow spots of softening. In the head is fatty softening, and a hemorrhagic infiltration extending into the surrounding tissue. At the back of the pancreas a narrow line of hemorrhagic and necrotic tissue; beneath it the duct, with necrotic wall. Left kidney and supra-renal capsule showed extensive subperitoneal hemorrhage. The microscopic examination of the pancreas showed necrosis of the fat-tissue with hemorrhagic processes in the tissue surrounding the fat-lobules.
LXX.....	Foster and Fitz: MS. Notes, 1887.	M.	59	Weight, 200 lbs. Strong and healthy. Two weeks ago thrown from carriage, but did not consider himself injured.	The attack began with intense pain in the left abdomen, without fever, apparent improvement for 3 days, then labored and jerking breathing, rapid, extreme exhaustion, and death in ten days after the onset of the pain.	The pancreas and mesentery showed a gangrenous parapancreatitis, and necrosis of the mesenteric fat-tissue.

Until two weeks before she entered the hospital she was able to replace the umbilical hernia. Since then the swelling and pain have increased.

On the day following her admission as patient she vomited after breakfast, and was seized with a severe paroxysm of colic. The pulse became small and flickering. On the following day there were nausea and bilious vomiting, the pulse remained very weak, at times not perceptible, and the face was pinched and anxious. The temperature was not elevated. On the third day the vomiting had ceased, but the face was flushed; the temperature, 100.8° F.; and the pulse, 144. She became comatose the next day and died. Pallor, gasping respiration, a temperature of 100.8° F., and a pulse of 124 were recorded. The coils of intestine in the immediate vicinity of the pancreas were united together, and to the diaphragm, by recent fibrinous adhesions. On removing these the pancreas was found to be doubled in size, of a dark-red color, and of a somewhat diminished density. On section, the tail was of a nearly uniform red color, soft, and its

tip was shreddy. The duodenal portion was of normal density and of a mottled red and gray color.

The splenic vein was filled with a reddish thrombus, in places softened at the centre. The under-surface of the diaphragm presented a dirty grayish-white, shreddy appearance. A section through the diaphragm showed it to be four times as thick as usual, and to contain numerous small collections of dirty-gray, puriform fluid. The diaphragmatic tissue was quite shreddy. There was an acute fibrinous pericarditis and a sero-fibrinous pleurisy. The umbilical hernia was omental and adherent.

Case LXVII. has the following record: The patient was an Irish laborer, forty-nine years of age; abundant fat-tissue.

In the past three years he has had three attacks of jaundice, with bilious vomiting, severe pain and tenderness over the xiphoid cartilage. He has suffered also from severe paroxysms of abdominal pain, and had been told by a physician during the past winter that he had passed a gall-stone.

After dinner he suffered from a burning sensation in the stomach, followed by nausea and severe abdominal pain, not paroxysmal but increased on motion. He became jaundiced on the next day and vomited a dark-green fluid, and considerable mucus. For the subsequent three days the vomiting persisted, and there were frequent gaseous and bitter eructations, also several loose, dark-green dejections.

He entered the hospital on the fifth day. The jaundice was conspicuous; the abdomen was resonant, except in the right flank, and sensitive. The pulse was 100, and the temperature rose abruptly from 97.4° F. to 100.8° F. During the subsequent four days the diarrhœa persisted. The urine contained a trace of albumen and a variety of casts. The pulse varied from 120 to 150, the respirations were very rapid, and the temperature remained moderately elevated.

On the eighth day he dressed himself, but did not seem conscious of his actions. He became mildly delirious on the following day, and while trying to escape from the ward fell forward, was temporarily unconscious, and his pulse could not be counted. The temperature became subnormal, but rose to 100° F. in the evening. On the tenth day, while trying to leave the bed, he fell to the floor, his pulse became weaker and more rapid, his breathing resembled the Cheyne-Stokes rhythm, and he died comatose.

The posterior wall of the stomach and the upper part of the mesentery were united by fibrinous adhesions to the pancreas, which lay in a cavity, within a spongy meshwork, infiltrated with dirty-green fluid. The pancreas was dark brown, dry, and firm. On section the lobules were indistinct, and the surface granular. Numerous opaque-white patches were seen, resembling those to be described in connection with the abdominal fat-tissue. The splenic vein contained a mixed thrombus four inches long and one-half the thickness of the little finger, and continued into several of the pancreatic branches. The spleen was soft and small. The liver was moderately granular and fatty. The gall-bladder was contracted about several calculi, the largest nearly the size of the end of the thumb, and projecting into the cystic duct. The walls were thick and tough; the mucous membrane thin, and streaked with opaque-white lines. The cystic and common ducts were dilated.

The subperitoneal fat-tissue of the abdominal wall, mesentery, omentum, and perinephritic region contained numerous superficial and deep-seated small, circumscribed, rounded, opaque-white, and saffron-colored patches. In general they were elongated, measuring an inch by a quarter of an inch. Rarely they were nodular, as large as a filbert, and on section contained dark-brown, discolored centres. Sections of the frozen fat-tissue showed numerous cavities containing a shreddy tissue, infiltrated with opaque-pink fluid of creamy consistency. Microscopical examination of the fresh specimens showed numerous leucocytes and large round-cells, with granular detritus, opaque-white specks, and bundles of small acicular or rod-like crystals.

There was nothing abnormal in the appearance of the stomach or intestines.

The microscopic examination of the hardened pancreas shows a small quantity of interlobular fat-tissue. In this are numerous islets of necrosis, their appearances being essentially the same as those found in the parapancreatic fat-tissue.

The larger ducts are filled with clumps of coherent, detached, cylindrical epithelium, with distinctly stained nuclei.

The gland-cells in certain parts, especially in the immediate vicinity of the necrotic fat-tissue, are swollen, granular, confluent, and without evident nuclei. The outlines of the acini are irregular or indistinct. Certain of the lobules present a diffused infiltration of round-cells. Many of the acini show a central accumulation of homogeneous hyaline material, with corresponding flattening of the gland-cells.

Sections of the subperitoneal and parapancreatic fat-tissue present numerous patches, varying in extent and shape, all more or less rounded, oblong, or leaf-like. They are sharply defined by a limiting zone, varying in width, of small, round-celled infiltration between the fat-cells. Next this cellular layer is often found a narrow, orange-colored streak, in which are frequent granules and round clumps of small, orange-colored acicular crystals. Within the patch the outlines of the fat-cells are often distinct over considerable areas, but elsewhere are almost wholly, if not entirely, obliterated by the clusters of large and long acicular crystals and granular material. These crystals were isolated, dissolved, and recrystallized by Dr. Harrington, assistant in chemistry at the Harvard Medical School, and are pronounced by him to be identical with those obtained from ordinary tallow.

In addition to the crystals and granules, bacteria were found, both as circumscribed colonies within, and as diffused accumulations without, the patches.

In the fat-tissue surrounding the patches of necrosis are occasional hemorrhagic spots, with distinct outlines of red blood-corpuscles. Small and irregular patches of leucocytes, without intercellular substance, are to be seen, occupying more space than that of several fat-cells.

Occasionally, elongated bands are found considerably wider than any visible blood-vessels. They are composed of agglomerated round-cells, with solitary larger corpuscles containing granular pigment. At each side of the central streak are numerous isolated, round and larger, flat, polygonal cells with large nuclei. These, in turn, are defined externally by a margin of clustered leucocytes. Arteries and veins are free from obvious changes.

The following record of Case LXX. is given as fully as possible. It is to be regretted that neither the specimen nor the detailed description of the pancreas was preserved. A gentleman, fifty-nine years of age, temperate, strong, and healthy, weighing two hundred pounds, was thrown from his carriage, but did not consider himself injured. Four days later he was seized with intense pain in the left abdomen, associated with nausea and vomiting. At the outset the pulse was 80, and the respiration 24. There was no fever at any time. After a few days the pain and tenderness were relieved. From the outset extreme exhaustion was a conspicuous symptom. Eventually rapid and labored breathing came on, and the patient died on the tenth day. A memorandum on the back of the letter accompanying the specimens, and giving the clinical details, states that the conspicuous lesions were a gangrenous peripancreatitis and necrosis of the mesenteric fat-tissue. From the lack of further details the question might be raised as to the exact method of origin of the gangrene and necrosis. At the time, I was satisfied that the case was analogous to that which immediately precedes, viz., Case LXVII.

Of these fifteen cases seven were males and eight females. Their ages were as follows:

Years of age.	Number of cases.
From 22–25	1
" 25–30	1
" 30–35	1
" 35–40	2
" 40–45	2
" 45–50	2
" 50–55	2
" 55–60	2

Past middle life	1
	15

They were from all walks and conditions of life. Five were very fat, one was decidedly lean; five were strong, and two of them were addicted to alcoholic drinks.

Eight of these patients had been subject to earlier more or less repeated attacks of digestive disturbance. These were always attended with pain, usually referred to the region of the stomach or stated to be biliary colic. They were frequently accompanied with vomiting, and, in one-third of the number, with jaundice. Constipation, or irregular defecation might occur, and in the latter case the stools were black.

At first sight the etiological importance of perforating gastric ulcer and of gall-stones seems immediate, as illustrated by Cases LVII., LVIII., and LXVII.

The comparison of these cases with others in the series would suggest that these affections were more important from the associated inflammation of the mucous membrane, with its opportunity of extension into the pancreatic duct, than from the actual or possible perforation of the biliary or digestive canal.

A traumatic cause for the fatal illness was possible in two instances.

In the one the patient was seized with a sudden pain in the lower abdomen, while turning a handspring, a week before the fatal illness. In the other the patient was thrown from his carriage five days previous. One person was seized with her attack while under treatment for an umbilical hernia of two years' duration. A mid-day meal and a hard day's work were each the immediate antecedent of the attack.

The illness usually, in four-fifths of the cases, began suddenly, without definite cause, with abdominal pain. This was rarely slight, but often intense and severe. It was referred to the stomach, left hypochondrium, navel, mid-abdomen, and left loin and back. The pain might be constant or paroxysmal like a biliary colic, and a diagnosis of gall-stones was made in one instance.

Vomiting was the next symptom of importance, being recorded in three-fifths of the cases. Partly digested food was ejected, or a viscid or slimy fluid, often green, sometimes black or bloody. Constipation was, at times, so conspicuous that, in connection with the other symptoms, a diagnosis of intestinal obstruction was made in three cases, and laparotomy performed in two. On the contrary, frequent bilious stools might occur.

The urine might contain albumen and casts. In one case an excess of indican was repeatedly sought for—in vain.

Jaundice, usually slight, occurred after a few days in one-fifth of the cases.

Chills were occasional, sometimes at the onset, and fever was frequent after a few days. The temperature was likely to be low, in the vicinity of 100° F., although it might be as high as 104° F. There might be no conspicuous fever throughout the course of the disease.

Swelling of the abdomen was present in one-half of the cases, usually occurring as a late symptom.

It might be slight or enormous, general, or limited to the epigastrium, or to the left half, where a fluctuating tumor was to be recognized. The abdominal swelling was usually tympanitic, although dulness might be present in the flanks. The spleen was palpable in a single instance, and the parotid became acutely swollen in another case.

As the disease ran its course weakness became apparent. Vomiting, perhaps diarrhœa, and abdominal pain were noticeable, suggestions of peritonitis were frequent, and symptoms of collapse were likely to take place, being followed more or less rapidly by death, which occurred as follows:

On the 4th day in	1	case.
" 5th "	1	"
" 10th "	3	"
" 13th "	1	"
" 15th "	1	"
" 18th "	1	"
At the end of 3 weeks in	1	"
" 5 "	1	"
" 7 "	1	"
" 8 "	1	"
Not stated in	1	"

Two patients recovered with the discharge of a slough through the bowel, one at the end of eight weeks. One of these patients was living seventeen years later.

The diagnosis lay between intestinal obstruction, biliary calculi, and peritonitis.

The appearance of the pancreas varied according to the duration of the disease. About the fourth day[91] the pancreas may be doubled in size, dark red, and of somewhat diminished consistency. It may be red, on section, or mottled red and gray. The tip may be shreddy, or the entire gland may be transformed into a dark, slaty-colored, stinking mass. The adjacent parts may be infiltrated with a discolored, purulent fluid, or the coils of intestine near the pancreas may be united by recent adhesions together and to the under-surface of the diaphragm.

The latter may show a dirty grayish-white, shreddy appearance, and its thickened substance may contain small collections of dirty-gray puriform fluid, the tissue itself being quite shreddy.

On the tenth day[92] the pancreas may be dark brown, dry, firm. It may have a hemorrhagic coating or lie in a sponge-like meshwork infiltrated with dirty-green fluid.

On section there may be dry hemorrhagic masses, with yellow spots of softening, or the lobules may be indistinct, with intervening opaque-white patches, like those to be found in the neighboring fat-tissue. The hemorrhagic infiltration may extend beyond the gland. The wall of the duct and the overlying tissue may be necrotic and hemorrhagic. The perinephritic fat and that near the suprarenal capsule may contain extensive hemorrhages.

Toward the end of the second week[93] the pancreas may be a soft, black, shreddy, sloughy, gangrenous mass, the central part being incapsulated by the peripheral portion. Between the pancreas and the transverse colon may be a large quantity of chocolate-like fluid, and large, bluish-black clots. Or the tail and a part of the body may be soft, gray-discolored, and infiltrated with a thin, ichorous fluid, while the parapancreatic tissue is partly purulent and partly ichorous.

A few days later[94] the pancreas may be a thin, flabby, friable, grayish band, lying in a cavity behind the stomach and attached by a few shreds to the omental wall. The cavity may contain ichorous fluid and communicate with the stomach by several openings with frayed edges.

At the end of three weeks[95] the dark-brown pancreas may lie nearly free in the omental cavity, attached only by a few rotten shreds of fibrous tissue. The cavity may contain abundant ichorous bloody fluid, and communicate with the duodenum. During the fourth and fifth weeks the pancreas may be discharged as a slough from the bowels.

In the fifth week[96] the pancreas may lie free, as if macerated, in a cavity extending behind the cæcum and descending colon, on both sides of the spine, as far as the pelvis. The contents may also be a greasy, grayish-yellow detritus, with fragments of necrotic fat-tissue nearly as large as hens' eggs. The latter are apparently seques-

trated from spaces with walls of a dark-brown or iron-rust color.

At the end of seven weeks[97] the pancreas may be transformed into a cylindrical, shreddy mass of brownish-black, friable tissue. This may lie in the omental cavity, which is filled with offensive, black fluid and communicates with the stomach and jejunum.

Thrombosis of the splenic vein frequently accompanies the pancreatic lesion, and is usually parietal. The thrombus in the early stages is soft and dark red, or it may be of a reddish-gray color. It has been found partly puriform, and extending to the portal vein, at the end of the second week.

A little later it has been found completely obstructing. The spleen may be soft, and is either large or small. Disseminated fat-necroses are often seen.

From the frequent mention of the position of the pancreas in the omental cavity, filled with ichorous pus, it is evident that an acute peritonitis with liquid exudation is a frequent, if not the usual, occurrence. The pus may be prevented from entering the general peritoneal cavity by adhesive obliteration of the foramen of Winslow.

Peritoneal adhesions between coils of intestine are not infrequent, especially in the vicinity of the root of the mesentery. A general suppurative peritonitis is of comparatively rare occurrence.

The inflammatory process may be extended to the pleural and pericardial cavities, and an acute leptomeningitis has been found on the thirteenth day. At a late stage of the disease, death may result from pulmonary embolism.

The possibility of an arrest of the processes resulting in pancreatic necrosis and parapancreatitis is evident from Case LX. Although the patient died of diabetes, the symptoms of which lasted at least a year, the tail of the pancreas, was flabby and macerated, and its tip lay free in a cyst arising immediately from the pancreatic capsule.

It is obvious from the anatomical appearances in this group of cases of gangrenous pancreatitis, para- and peripancreatitis, that the lesions are associated with a hemorrhagic pancreatitis in a considerable number of cases. In at least one-half there is mention of hemorrhage into the pancreas or of such discoloration as to suggest a hemorrhage.[98]

A comparison of the clinical history of this series of cases with that of hemorrhagic pancreatitis will show a strong resemblance in predisposing causes, and in the nature of the symptoms. These are essentially identical in nearly all. In many of the remaining cases the symptoms are those which would favor the diagnosis of a hemorrhagic pancreatitis.

In any event, they represent the termination of acute pancreatitis in gangrene, with an extension of the process to the continuous tissue.

Viewing the subject from the anatomical side, it is evident that cases of hemorrhagic pancreatitis may terminate fatally within a few days, either with or without necrosis of the gland and parapancreatic fat-tissue. They may also prove fatal in from one to four weeks, in consequence of an extension of the disease to the para- and peri-pancreatic tissues, with gangrene of the parts concerned.

Disseminated Fat-necrosis.—Considerable prominence has necessarily been given to the necrosis of fat-tissue associated with pancreatic inflammations.

Hooper[99] probably intended to describe the appearances due to this condition, but Ponfick[100] first distinctly recognized the condition. He called attention to a disseminated necrosis of bone-marrow in a case of empyema and extensive amyloid degeneration. The appearance was that of innumerable, submiliary, yellowish-white specks in the amber-colored marrow. They proved to be composed of an agglomeration of large cells crowded with fine granules. These were enormous granular corpuscles, which, from their size and shape, were regarded as identical with fat-cells. There were also narrow and elongated, fatty-degenerated cells, so disintegrated in many places as to form a finely granular detritus. Ponfick attributed these spots of necrosis to a fatty degeneration of the marrow.

Balser,[101] who became an assistant of Ponfick, then professor at Göttingen, found similar appearances in the marrow and in the subpericardial fat, each in an old man. In the examination of twenty-five unselected cases, he found such patches in the region of the pancreas in five instances. Two of these patients died of cancer of the stomach, and the remaining three were cases of pulmonary consumption, hepatic cirrhosis, and aortic endocarditis respectively. There remain two additional cases in which he found fat-necrosis.[102]

These he regarded as illustrative of the fatal effect of a disease—fat-necrosis—which, when extensive, was associated with old and fresh hemorrhage. Such hemorrhages near the pancreas might produce death in the manner resembling that described by Zenker as pancreatic apoplexy. He regarded the fat-necrosis as the result of an excessive growth of fat-tissue which destroyed the tissue it surrounded. From its association it was a special source of danger to fat persons. His conclusion is:[103] "An excessive growth of the fat-cells near the pancreas occurs in many men. It may become so excessive, in very fat people, that a large part of the abdominal fat dies, and it thus proves fatal either on account of the quantity destroyed or the associated hemorrhage."

Chiari[104] had also found fat-necrosis associated with pancreatic disease,[105] although in his published report he made no note of the characteristic appearances. He confirmed Balser's statements concerning the occurrence of fat-necrosis in and near the pancreas. Since he had observed it in five out of six cases of pancreatic disease, a certain connection between the two was suggested. Three of these were cases of sequestration of the pancreas. The remaining three were a phthisical diabetic, a case of chronic Bright's disease and interstitial pneumonia, and an infant with congenital syphilis. He found no evidence of an excessive circumscribed growth of fat-tissue as claimed by Balser, but regarded the necrosis as a degenerative process, analogous to the retrograde metamorphosis in other tissues, and the result of a severe marasmus. He admitted it as a cause of pancreatic hemorrhage, and that it might, hence, prove fatal. He did not regard the sequestration of the pancreas as the result of this necrosis, since he could not understand how extensive circumscribed necrosis about the pancreas could isolate so large an organ.

Finally, Van Giesen[106] presented to the New York Pathological Society microscopical sections illustrative of fat-necrosis. They came from the pancreas of a woman, eighty years of age. There were two nodules, the larger 5 mm. in diameter. Nothing is stated with reference to any associated lesions, and the necroses were regarded as degenerative. There is a general agreement as to the appearance of these nodules. They are multiple, disseminated, are found in the subperitoneal fat-tissue of the abdominal wall, mesentery, omentum, and in that within and around the pancreas. Chiari[107] found them also in the subpericardial, subpleural, and subcutaneous fat. Their presence in marrow has already been mentioned.

Such nodules were present in one case of pancreatic hemorrhage, certainly in one, probably in two, cases of acute suppurative pancreatitis. They were seen in six cases of hemorrhagic and in six of gangrenous pancreatitis. These nodules, in most of the cases, occurred in great numbers, the smallest not larger than a pin-head, and strongly suggestive of miliary tubercles or malignant

new formations. The largest were of the size of a hen's egg. All were more or less rounded, of an opaque-white or yellowish-white color, and of soft, tallowy consistency. They occurred alone or in groups, superficially and deep-seated. The smallest were often surrounded by an injected, vascular wreath, while many were bounded by a distinct, narrow, reddish-brown zone indicative of hemorrhage.

Chiari[108] found the larger nodules (although he does not state in which of his six cases) incrusted with lime, and surrounded by a distinct, fibrous capsule, from which threads occasionally ran into the surrounding fat-tissue. The tallowy material could be readily picked out of these nodules, and, when examined microscopically, consisted largely of acicular crystals resembling those found in fat, in addition to fat-drops and a granular detritus. Dr. Harrington's micro-chemical examination of these crystals shows their identity with those obtained from tallow. He regards them as stearine. In this view he confirms the conclusion reached by Balser.[109]

The microscopical appearances have already been described in sufficient detail.

Balser states[110] that his examination shows that the same process is concerned in the mild and fatal cases. Neither he nor Chiari was able to find any evidence of a bacterial or mycotic process, nor was the latter able to discover any changes in the neighboring vessels. The microscopical appearances found in Case LXVII. make evident certain features in the more serious fat-necrosis which supplement the results described by other observers. Tracts of round-celled infiltration were found at the border of the patches. Chiari also states that the fibrous threads continued from the capsules were infiltrated with round-cells. The surrounding fat-tissue gave frequent evidence of an acute lymphangitis, of abscesses, and of thrombosis. Bacteria were found in and near the patches of necrosis. They were likewise present in a neighboring vessel and in a venous thrombus. The association of these appearances with the evidences of fat-necrosis indicate most directly that the latter condition, in fatal cases at least, instead of being simply the result of a hyperplasia or of a degeneration, is connected with an acute inflammatory process somewhat akin to the phlegmonous inflammation of the subcutaneous fat. The cause of its dissemination would thus, probably, depend upon the transfer of an infecting material, either through vascular currents, especially lymphatics, or by direct inoculation of the peritoneum in case of the superficial nodules. The multiple disseminated fat-necrosis found associated with fatal pancreatic disease is thus to be regarded as the result of the inflammation of the fat-tissue extended from the pancreas or its vicinity. The pancreas is usually the seat of the primary process, but the necrotic inflammation of the fat-tissue may be secondary to a possible primary lesion of the biliary tract or stomach, as suggested by Cases LVII. and LVIII.

The spots of dead fat-tissue observed in the marantic cases may be degenerative, as claimed by Ponfick and Chiari. They certainly are neither necessarily nor exclusively found in fat persons. There is no confirmatory evidence of their hyperplastic nature. The inflammatory fat-necroses, in most cases, were associated with evidences of putrefactive conditions.

It would thus appear that there is a necrobiotic necrosis of the fat-tissue, and an inflammatory necrosis, the latter tending to become gangrenous, both of which may be found within or near the pancreas. The inflammatory and gangrenous varieties are of especial importance in permitting the sloughing of the pancreas, and in most instances are the result of an acute inflammation of this gland.

Although the serious varieties of fat-necrosis may be recognized as causes for sequestration of the pancreas, their relation to pancreatic hemorrhage must be expressed in different terms from those employed by Balser and Chiari.

A simple, necrobiotic fat-necrosis may be associated with fatal pancreatic hemorrhage, as suggested by Case V., but there is no necessary etiological significance in this association. Most fatal cases of pancreatic hemorrhage occur without either variety, and the simple necrosis usually takes place without hemorrhage.

When the severe varieties of fat-necrosis accompany pancreatic hemorrhage, inflammation of the pancreas is present. The fat-necrosis cannot be regarded as the essential cause of the hemorrhage in such cases, since it occurs in suppurative pancreatitis when there is no hemorrhage in the pancreas. Furthermore, when hemorrhages are found near the necrotic patches, they are usually very slight, and limited to the immediate vicinity of the patch.

The evidence presented in this paper is intended to show that: Acute inflammation of the pancreas is a well-characterized disease, of much greater frequency than has generally been thought. Its appreciation is deemed of consequence, because it usually represents a serious complication of what is generally regarded as a relatively simple affection, viz., gastro-duodenitis. It is an important cause of peritonitis, and one readily overlooked. It has been repeatedly confounded with acute intestinal obstruction, and has thus led in several instances to an ineffective laparotomy.

Acute pancreatitis commonly originates by the extension of a gastro-duodenal inflammation along the pancreatic duct. It may also be induced by the occurrence of hemorrhage in the pancreas, which, in turn, may be of traumatic origin, although usually arising from unknown causes. The pancreatic hemorrhage may likewise be secondary to inflammation of the pancreas.

The anatomical varieties are the suppurative, hemorrhagic, and gangrenous. The first may be acute, but is usually subacute or chronic. The second is generally peracute or apoplectiform. The gangrenous variety runs an acute course.

Suppurative pancreatitis may result in an evacuation of the abscesses into the stomach or duodenum. They may open into the cavity of the great omentum, which, transformed into a large peritoneal abscess, may, in turn, open into the digestive tract. Pylephlebitis and abscesses of the liver may result. Disseminated fat-necrosis is comparatively infrequent.

Hemorrhagic pancreatitis usually proves fatal in from two to four days. The gross lesions are then those of hemorrhage within and near the pancreas, extending into the subperitoneal fat-tissue, perhaps as far as the pelvis. Disseminated fat-necrosis is common.

Gangrenous pancreatitis, although it may be secondary to a perforating inflammation of the gastro-intestinal or biliary tracts, usually results from a hemorrhagic pancreatitis, and proves fatal in the course of a few weeks. The gangrenous processes extend to the parapancreatic tissue, and produce more or less complete sequestration of the pancreas. The peritoneal wall of the omental cavity becomes inflamed, that covering the pancreas may be destroyed, and the sequestrated gland may lie in the omental cavity, soaked in pus, and attached only by a few shreds. Both pus and pancreas may be discharged into the intestine. Splenic thrombo-phlebitis is not uncommon, but hepatic abscesses are rare. Disseminated fat-necrosis is frequent.

The common symptoms of acute pancreatitis are sudden, severe, often intense, epigastric pain, without obvious cause, in most cases followed by nausea, vomiting, sensitiveness, and tympanitic swelling of the epigastrium. There is extreme prostration, frequent collapse, low fever, and a feeble pulse. Obstinate constipation for several days is the rule, but diarrhœa sometimes occurs. If the case does not end fatally in the course of a few days, recovery is possible, or a recurrence of the symp-

[108] Loc. cit., 299. [109] Loc. cit., 522. [110] Loc. cit., 528.

toms in a milder form takes place, and the characteristics of a subacute peritonitis are developed.

It is evident that all treatment, at the outset, can be nothing but palliative. With the establishment of an omental peritonitis is the opportunity for the surgeon. The possibility of the successful removal of the gangrenous pancreas is suggested by the healthy condition of a patient seventeen years after he had discharged this organ from his bowels.

The spots of dead fat-tissue observed in the marantic cases may be degenerative, as claimed by Ponfick and Chiari. They certainly are neither necessarily nor exclusively found in fat persons. There is no confirmatory evidence of their hyperplastic nature. The inflammatory fat-necroses, in most cases, were associated with evidences of putrefactive conditions. It would thus appear that there is a necrobiotic necrosis of the fat-tissue, and an inflammatory necrosis, the latter tending to become gangrenous, both of which may be found within or near the pancreas. The inflammatory and gangrenous varieties are of especial importance in permitting the sloughing of the pancreas, and in most instances are the result of an acute inflammation of this gland.

Although the serious varieties of fat-necrosis may be recognized as causes for sequestration of the pancreas, their relation to pancreatic hemorrhage must be expressed in different terms from those employed by Balser and Chiari.

A simple, necrobiotic fat-necrosis may be associated with fatal, pancreatic hemorrhage, as suggested by Case V., but there is no necessary etiological significance in this association. Most fatal cases of pancreatic hemorrhage occur without either variety, and the simple necrosis usually takes place without hemorrhage.

When the severe varieties of fat-necrosis accompany pancreatic hemorrhage, inflammation of the pancreas is present. The fat-necrosis cannot be regarded as the essential cause of the hemorrhage in such cases, since it occurs in suppurative pancreatitis when there is no hemorrhage in the pancreas. Furthermore, when hemorrhages are found near the necrotic patches, they are usually very slight, and limited to the immediate vicinity of the patch.

Conclusions.—The evidence presented in this paper is intended to establish the fact that acute inflammation of the pancreas is both a well-characterized disease and one which is much more frequent than is generally thought. It is of great consequence that it should be recognized, for the following reasons: It represents a serious complication of what, by itself, is a relatively simple affection, viz., gastro-duodenitis; it is an important cause of peritonitis, and one readily overlooked; it has been repeatedly confounded with acute intestinal obstruction, and has thus led, in several instances, to an ineffective laparotomy—an operation which, in the early stages of this disease, is extremely hazardous.

Method of Origin.—Acute pancreatitis commonly originates by the extension of a gastro-duodenal inflammation along the pancreatic duct. It may also be induced by the occurrence of hemorrhage in the pancreas. This may be of traumatic origin, although usually arising from unknown causes. The pancreatic hemorrhage may likewise be secondary to inflammation of the pancreas.

Pathological Anatomy.—The anatomical varieties are the suppurative, hemorrhagic, and gangrenous. The first may be acute, but is usually subacute or chronic. The second is generally peracute or apoplectiform. The gangrenous variety runs an acute course.

Suppurative pancreatitis may result in an evacuation of the abscesses into the stomach or duodenum; or they may open into the cavity of the great omentum, which, transformed into a large peritoneal abscess, may, in turn, open into the digestive tract. Pylephlebitis and abscesses of the liver may follow. Disseminated fat-necrosis is comparatively infrequent.

Hemorrhagic pancreatitis usually proves fatal in from two to four days. The gross lesions are then those of hemorrhage within and near the pancreas, extending into the subperitoneal fat-tissue, perhaps as far as the pelvis. Peripancreatitis may be expected, and disseminated fat-necrosis is common.

Gangrenous pancreatitis, although it may be secondary to a perforating inflammation of the gastro-intestinal or biliary tracts, usually results from a hemorrhagic pancreatitis, and proves fatal in the course of a few weeks. The gangrenous processes extend to the parapancreatic tissue, and produce more or less complete sequestration of the pancreas. The peritoneal wall of the omental cavity becomes inflamed, that covering the pancreas may be destroyed, and the sequestrated gland may lie in the omental cavity, soaked in pus, and attached only by a few shreds. Both pus and pancreas may be discharged into the intestine. Splenic thrombophlebitis is not uncommon, but hepatic abscesses are rare. Disseminated fat-necrosis is frequent.

Symptoms.—The common symptoms of acute pancreatitis are sudden, severe, often intense, epigastric pain, without obvious cause, in most cases followed by nausea, vomiting, sensitiveness, and tympanitic swelling of the epigastrium. There is prostration, often extreme, frequent collapse, low fever, and a feeble pulse. Obstinate constipation for several days is the rule, but diarrhœa sometimes occurs. If the case does not end fatally in the course of a few days, recovery is possible, or a recurrence of the symptoms in a milder form takes place, and the characteristics of a subacute peritonitis are developed.

Diagnosis.—The symptoms are essentially those of a peritonitis beginning in the epigastrium and occurring suddenly, during ordinary health, without obvious cause. The diagnosis, therefore, is based on pain, tenderness, and tympany limited to the region of the pancreas, and on the gradual development of a deep-seated peritonitis in the same place.

Differential Diagnosis.—The differential diagnosis lies, practically, between an irritant poison, perforation of the digestive or biliary tract, and acute intestinal obstruction. An irritant poison is excluded by the history of the case and by the examination of the vomit.

Perforating ulcer of the stomach or duodenum is to be excluded by the absence of pain after eating, hemorrhages from the digestive canal, and cachexia. Acute perforation of the transverse colon is rare, and the resulting peritonitis progresses more rapidly, and is likely to be general. Perforation from gall-stones is usually preceded by attacks of biliary colic and jaundice, while the seat of the pain is rather in the region of the gall-bladder than in that of the pancreas.

Acute intestinal obstruction is most likely to give rise to doubt. It is to be eliminated by determining, through injection, the patency and capacity of the large intestine, by the rarity in the epigastrium, of an obstructed small intestine, by the immediate presence of localized tenderness, and by the usual absence of a conspicuous general tympany or limited distention of intestinal coils.

Treatment.—It is evident that all treatment, at the outset, can be nothing but palliative. With the formation of pus in the omental cavity comes the opportunity for the surgeon. The possibility of the successful removal of the gangrenous pancreas is suggested by the healthy condition of a patient seventeen years after he had discharged this organ from his bowels.

An unexpectedly early verification of the above conclusions has occurred within the week following the delivery of this lecture.

The case was that of a well-known gentleman of Boston, and presented so fully the symptoms above mentioned, that, when called, as consultant, I was able to make a diagnosis of acute pancreatitis, which was eventually substantiated.

The following is a brief summary of the essential features of this case, which will, hereafter, be more fully reported:

The patient was suddenly seized, February 19th, while apparently in his usual good health, with a severe pain and tenderness a short distance above and to the left of the navel. This was followed by vomiting and a certain degree of prostration. The administration of nearly a grain of morphia gave relief. I saw him in the evening, and during the subsequent two days of his life. He died on the third day. The localized pain was more or less constant, with occasional severe twinges, and was also to be elicited by intercostal pressure in the splenic region. The sensation of a constricting band in the epigastric region was likewise mentioned. At the close of the second day the lower abdomen became sensitive in spots. There was vomiting on the first day, but not later, and the bowels were confined. The abdomen was somewhat distended and dull, except in the epigastrium. The pulse was moderately accelerated, and the temperature slightly elevated.

The diagnosis lay between acute mechanical intestinal obstruction, perforative peritonitis, and acute pancreatitis. The majority of the consultants agreed to the first as the most probable condition, and advised a laparotomy, which was performed on the third day. Spots of fat-necrosis were seen in the omentum, but there was no evidence of mechanical obstruction.

At the post-mortem examination the characteristic appearances of hemorrhagic pancreatitis were found, also numerous spots of disseminated fat-necrosis.

STRETCHING THE SPHINCTER ANI AS A METHOD OF CURE IN OBSTINATE CONSTIPATION.[1]

By CLEMENT CLEVELAND, M.D.,
NEW YORK CITY.

The operation of stretching the sphincter ani for the cure of fissure of the anus is one that has been long in vogue and rightfully holds its position as the quickest and surest method of relieving that troublesome affection.

It is the custom of some operators to stretch the sphincter after perineorrhaphy, to keep the muscle in a quiescent state during the first few days, the belief being that thus a greater chance of complete union is assured. I have had faith in it myself, and often practise it where I think there is any risk from such a source.

I long ago observed that in many cases thus operated upon, in which obstinate constipation had existed, that could not be attributed to pouching of the posterior wall of the vagina, the constipation was cured. I noticed the fact, without at the same time thinking of its application to cases of constipation where no fissure existed, till April of 1884, when a case came under my care that baffled every effort to relieve; it was then it occurred to me to stretch the sphincter.

The patient was a young woman, twenty-five years of age, and unmarried, whose occupation was a sedentary one. She had been bred in affluence, but loss of property had compelled her to seek her own living, and she secured employment as an amanuensis. Her sedentary life, with much worry and anxiety, led to carelessness about the requirements of health. She took little or no exercise, and used cathartics and enemata to relieve the bowels. When I first saw her the trouble had lasted several years, and had become so difficult to relieve that she was fairly desperate. It was the worst case I have met with. There was no abnormal sensitiveness of the sphincter. Examination revealed no fissure, the fæces were of good color, but hard and dry, and often broken up into scybala, and there seemed to be no intestinal secretion whatever. There was no discoverable obstruction in the pelvis or elsewhere. It was evidently the result of fixed habit and the constant use of cathartics and injections.

There are cases, I am aware, where the bowels are not relieved for days at a time and the person remains in good health, this being apparently the normal condition. Such, however, was not the case with the one I am now speaking of. She was in constant distress, though without actual pain.

The operation having been decided upon, the patient was placed in Sims' position and the sphincter thoroughly stretched, and so thoroughly was it done that some of the fibres of the external sphincter were torn. As an immediate result there was a prolapsus of the rectum, which, from its swollen turgid condition, was troublesome to keep replaced, till the patient had recovered thoroughly from the etherization. It is not necessary to stretch to the point of rupturing the muscle, even to a slight extent, though no apparent harm was done in this case. It is, however, difficult to avoid sometimes, the muscle giving way before the operator is aware. This patient was cured and has never had a return of the trouble.

Another case was that of a young woman, of about the same age as that of the previous patient, and she, too, had been suffering several years. In this case there was a complication of disorders; constant pain in the uterus and ovaries; constant desire, with inability, to relieve the bladder; menorrhagia and obstinate constipation. The uterine and bladder troubles were of late development.

Examination revealed a large, sensitive, anteverted uterus, with excessive sensitiveness in the region of the ovaries, and large fæcal accumulations in the rectum. There was pus and blood in the urine, and blood in large amount in each passage from the bowels.

She had been taking a small amount of morphia each night at bed-time.

To move the bowels she used a bottle of sweet-oil every other day. Cathartics, except in very large doses, had lost their effect. The oil seemed to produce a better result than anything else, so for some time she had been using that alone. The relief, even with this, was not perfect.

The urine was drawn every other day by catheter, and was sometimes allowed to remain in the bladder three and four days at a time. The condition of the patient can be imagined. Her nervous system was in a deplorable state. She was anæmic and had lost much flesh.

I attributed most of the pelvic symptoms to the obstinate constipation, from the constant pressure of large fæcal masses upon the intrapelvic vessels and nerves, and decided that something must first be done in that direction before attempting any treatment of the uterine and ovarian conditions. Accordingly the patient was placed under ether and the sphincter thoroughly stretched. In the after-treatment I used small injections of glycerine for a week or a little longer, after which there were daily evacuations for some time. With the relief of the rectum and colon, aided by local treatment and medication, the cystitis was cured and the uterine and ovarian trouble improved, though the constant pain and sensitiveness in one ovary—the right—continued. For this reason it was impossible for the patient to take exercise, and, notwithstanding the care and attention paid to her diet, she was troubled greatly by indigestion. At the end of two months there was a return of the constipation, as I feared there would be. Having experienced so much relief from the first operation, she was anxious to have it repeated. This was done, and followed, as before, by relief. The patient was growing stronger all this time, and the digestive functions were performing their work better; but winter came on and she was confined to the house much of the time. In the spring, after a period of four months, she began to experience some little difficulty with her stools, though constipation had not recurred to the same degree as before. During the winter my attention had been devoted to relieving the pain and sensitiveness in the ovaries, but with slight and only temporary success at any time. I had commenced

[1] Read at a meeting of the Practitioners' Society of New York, February 1, 1889.

to fear that the ovary would have to be removed; but, as a last resort, before coming to that, I decided to put in a seton. The patient was again etherized, and a deep seton, consisting of fifteen strands of twisted silk, was introduced over the right ovary, and afterward the sphincter again stretched. To cut short this part of the history, the seton began to afford relief almost at once, and the pain gradually disappeared. It was worn five months, though after the fourth month rarely was even a twinge of pain felt in the ovary. It was worn for so great a length of time because the patient was reluctant to have it removed, and because I wished to be sure of its permanent effect. It is now eight months since the seton was introduced and the sphincter stretched, and three months since the seton was removed. There has been no return of pain and sensitiveness in the ovary, and no return of the constipation. The patient appears perfectly well. Though the treatment of ovarian disease forms no part of the subject of this paper, yet I have introduced it here because the two conditions were so closely associated in the same patient, and because the constant pain in the ovary may have been, and probably was, a factor in the causation and continuance of the constipation.

I have had quite a large number of cases, ten in all, the details of which would add but little of interest in the discussion, and I therefore omit them. The first history related is of a typical case, and the second of a very unusual one. They serve my purpose as illustrations.

In but one case, the one last related, was the operation repeated, and here it would not have been necessary but for the complications presented.

The theory of the operation is, of course, simple and easy of explanation. When fæcal matter passes from the colon into the rectum, it there arouses the conjoined muscular action which is to expel it. The action of the sphincter muscles is twofold, that of a barrier to involuntary movement, and an aid to expulsion of fæces. The internal sphincter is merely an aggregation of intestinal muscular fibres, and the joint action of both sphincters, in aiding the expulsion of fæces, is the same as the peristaltic movements of the intestines, only much more powerful. Where obstinate constipation of long standing exists, the general condition is usually debilitated. The rectum is distended by hard, dry fæces. The sensibility of its nerves is blunted and the contractile power of its muscular fibres so enfeebled that, even with the aid of the expiratory muscles, it is unable to overcome the resistance of the sphincter to the passage of large fæcal masses. The sphincter is here a barrier merely. It is stimulated to excessive action by the hard mass packed up against it, and cannot grasp and aid in its downward movement.

Where the integrity of the sphincter is lost, as in complete rupture after childbirth, there is nothing to check the involuntary action of the rectal muscles, and involuntary evacuations are likely to result. Where the operation of stretching has been done, the sphincter, no longer able to contract forcibly, offers but a passive resistance to the passage of fæces. It can check the effect of involuntary action of the intestines, but not when the expulsive force of the expiratory muscles are brought into play.

And now a word as to the selection of cases for the operation. There are but few, no matter what the cause, whether of local or general origin, that are not, in my judgment, helped by it. But, as a curative agent, it is strictly applicable to cases whose causes are general, such as habit, improper diet, the abuse of cathartics, enemata, etc.

I do not advocate its employment indifferently. A careful investigation should be made, and an accurate diagnosis arrived at, if possible. The treatment does not end with the operation. It is really but the first step, while the after-management is most important. It enables the expiratory muscles to prevent the accumulation of fæcal matter, and gives the rectum time to recover its power and sensibility. It gives the digestive functions rest from the constant and disturbing effect of laxative medicines, and, above all, from the constipation itself, which certainly disturbs primary digestion, destroys appetite, and, in its remote effects, produces anæmia and wasting. Rest afforded to the digestive function, I reiterate for the sake of emphasis, is, perhaps, the most important factor in the cure.

As I have said, the after-care is as essential as the operation, and a physician cannot be too careful and positive in laying down rules that he should insist upon being followed. It is as easy for the patient to relapse into the former condition as it was to form the habit originally, if all causes which lead to the trouble are not sedulously avoided. Careful attention must be paid to diet especially. A suitable, and proper amount of exercise suited to each individual case should be insisted upon. The skin should be kept in an active condition by bathing or sponging with cool water daily. The importance of regularity of going to stool cannot be too strongly urged.

I have not attempted to look up the literature of this subject, and I do not know but that I am treating of an operation which others have previously done and described. I have, however, tried to keep informed, and do not think the operation had been done previous to my first case—strictly, I mean, for the purpose of curing constipation.

DR. DALTON AND THE NEW YORK PATHOLOGICAL SOCIETY.

By JOHN C. PETERS, M.D.,

NEW YORK.

Our distinguished ex-President, Dr. John Call Dalton, belonged to a very progressive medical family. His father was an excellent physician who trained his sons well. His brother, Dr. Edward, became eminent, and John greatly increased the family renown.

He graduated in medicine from Harvard in 1847, and immediately commenced a thorough study of practical physiology and comparative pathology. Before his time physiology had been largely speculative; he made it practical mainly by his great skill in vivisection. Some of his methods were destructive and seemed cruel, but they tended most surely to the welfare of the whole human and animal race.

He had rare gifts for such pursuits, and was equally expert with pen, pencil, scalpel, and microscope. He was also a great teacher; his lectures were finished discourses, always delivered in the most clear, graphic, and impressive language; his pamphlets are masterpieces; his text-books models of their kind; his larger works all became classical. His management of chemical, philosophical, and more dread apparatus was as dexterous as that of a magician; and very difficult experiments were always made with the ease and certainty of a conjurer.

He was preceded in his abstruse studies by Magendie, Claude Bernard, and others in Europe, but he was the pioneer of vivisection in this country, and was forced to be its public champion, year after year, before the Legislature, in order to save it from the bitter assaults of its malignant enemies. He was so small in stature and seemingly so delicate in frame that our great aldermen and assemblymen looked down upon him, at first with contempt, but finally in great admiration that so much bravery, wisdom, and eloquence could proceed from such a quaint and fragile little body. He was so strong in his science and his honesty, and such a master of convincing language that he swept away all factious opposition like idle wind. And when he showed them that all his seemingly cruel experiments could be carried out under the beneficent influence of anæsthesia, they promptly refused to declare his wonderful work either inhuman or unlawful. Thus the great lovers of sport became the great defenders of science.

He joined this Society in 1853, quickly took a great

lead in some of our most intricate and scientific work, and became one of our most earnest, precise, ingenious, and successful laborers. Of course our highest honors were soon showered upon him; he often represented us before other learned bodies, was elected Vice-President in 1857, and President in 1859, when he was only thirty-four years old. Some of the best beginnings of his great fame were made in our halls; some of the earliest as well as the latest plaudits which cheered him on in his toilsome but splendid career came from our voices; we were always ready to act as his shield and safeguard in the times of his greatest trials; and we were his willing stepping-stones, first to a professorship, and then to the Presidency of the College of Physicians and Surgeons. Need we add that he remained the warm and generous friend of this Society down to the last days of his busy life, and that we should cherish his name and fame among our most precious treasures.

He was a very earnest, honest, and industrious man. His honesty and industry made up the greatest part of his life and his religion; they were his greatest charms and strength. His was no slip-shod, nor yet a rough-and-ready search after truth, but a patient and relentless hunt. He tested and re-tested every step of his progress in such painstaking and varied ways that there was little chance left for error; and when Dalton announced a discovery we all knew it would never be entirely overthrown, or its great principles completely swept away. When he confirmed the discoveries of others we were satisfied. His researches extended from the very beginnings of life in the most insignificant creatures up to the completest functions of the most perfect men and animals. Graafian vesicles, hydatids, tapeworms, and Surinam frogs were traced through all their curious metamorphoses with the genius of an Ovid. He was a bachelor and wrote learnedly about ovaries, and then gave us the best book on the human brain that has ever been published.

Like Mr. Lincoln his face was not comely to look upon, and scarcely indicative at first view of his rare powers. It was not like a "white and alabaster image of his grandfather," but more like that of a yellow, sandy Scotchman, with a little flavor of his loving and canny little favorite companion. But to those who knew him well it gradually became charming; and his light, easy, graceful, and active body was not "a bale of cadaverous goods."

His manners were so unobtrusive that few strangers ever realized that he was a man of great force in large affairs; of much renown and still greater achievements; had long borne heavy responsibilities with great honor, and had completed great and varied enterprises both successfully and felicitously.

He could unbend occasionally and be a very pleasant and witty companion; but his delicate health long deprived him of almost all social pleasures. He bore his sufferings bravely and uncomplainingly, and we were somewhat prepared for his death, but our sorrow now is none the less.

The hands of death have fallen heavily upon us. The shades of Sands, Agnew, and Dalton still seem near by; and those of Clark, Flint, and Post not far off. They have gone out into solemn silence, and no real voice or sound can come from them. But they all had prosperous and beautiful lives, happy and spotless names, calm deaths, and immense fame. They were kind friends, teachers, and benefactors; they had an unceasing tribute of applause and admiration; love and sympathy follows them, and many and honored memories cluster around them.

THE SUSPENSION TREATMENT OF LOCOMOTOR ATAXIA has been recently widely advertised, both in lay and medical journals. Brilliant results are claimed for it in Charcot's clinic at Paris, where fourteen cases were treated with decided amelioration of symptoms. The reports suggest the "brilliant" results, as some time ago reported, of nerve-stretching.

NOTES REGARDING THE MANAGEMENT OF CHRONIC GASTRO-INTESTINAL CATARRH.

BY W. W. VAN VALZAH, M.D.,

NEW YORK.

(REPORTED BY CHARLES R. CRANDALL, M.D.)

THE object in reporting the following typical cases is to call attention to practical methods. The principles and methods set forth are comparatively simple, yet, as will be seen, they are sufficient to afford good results. Having proven to be of real merit in many instances, it is hoped that their utility will be more generally recognized, so that they will gain an established place in medical practice. Surely, whatever tends to help the physician in the cure of obstinate diseases, and is also capable of bringing relief to patients who have long experienced intolerable suffering, is worthy of recognition.

Chronic Catarrh of the Stomach.—Mr. H——, aged twenty-nine, of good family history, exemplary habits, and a lawyer by profession. In boyhood he lived in a malarious climate, and suffered more or less from fever and ague. At a very early age he began to show symptoms of indigestion, with which he has been troubled more or less ever since. Eight years ago serious symptoms of acidity of the secretions of the stomach, accompanied by pain and flatulence, began to develop. About three hours after eating he would have severe epigastric pain, a sense of burning and distress, followed by eructations of gas and sour fluids. Four years ago he had what was diagnosed to be an attack of acute catarrh of the stomach, attended by a great increase of all his former symptoms. During this attack he was sick in bed three weeks, and several weeks more elapsed before he regained his usual health. The chronic condition became so bad that he was obliged to make a radical change in his business and mode of living, and therefore engaged in "ranching" in Colorado. In this new and invigorating life he had an abundance of fresh air and exercise, and, as a result, was benefited. But, at best, he suffered more or less from catarrhal disease of the stomach, despite the fact that he guarded himself in every way and lived mostly on a regulated diet, such as he had found was best for him. He had already discovered that an animal diet, composed mostly of eggs and beef, agreed better with him than anything else. The trouble from which he suffered seemed to be limited to his stomach, for during all the years of his troubles his bowels remained in good condition. Last summer he had a brief run of what is known as "mountain fever," which prostrated him very much. As soon as the fever began to break, he had an attack of "catarrhal inflammation of stomach and bowels." As may be inferred, these conditions greatly aggravated the chronic diseases from which he had long suffered intolerable misery. In addition, prolonged suffering from gastric catarrh, repeated severe acute attacks, and mal-nutrition, all tended to break down his nervous system and give rise to alarming symptoms, such as great mental depression, headache, wakefulness, and irritability. It should be stated also, as a matter of fact, that during all these years he was under medical treatment more or less, and had sought health in every possible way. When he presented himself for treatment in October of 1888, he had a pale, tired look, was thin in flesh and very much debilitated. He complained of the nervous symptoms above described, and of pain and distress in his stomach, especially after meals. His tongue was coated, his appetite poor, and there was pain and tenderness over his stomach. He also had marked naso-pharyngeal catarrh. His bowels were in fairly good condition, but greatly distended with gas. Microscopic examination of his blood showed that it was in quite good condition. There was an almost entire absence of morbid products. Such was to be expected, for the blood does not show abnormal products to any extent in catarrhal disease of the stomach. It is during catarrhal, or long-standing functional and catarrhal, diseases of the bowels that the blood contains a large amount of the products of

fermentation and decomposition. This is owing to the fact that yeast-germs, and various alkaloidal products of decomposition are absorbed through the villi, lacteals, and blood-vessels of the intestines, whereas in the stomach the veins and arteries are the only means of absorption of normal and abnormal products. Urinary analysis showed a large quantity of biliary coloring matter in the urine, phosphates in excess, and a specific gravity of 1.032. Repeated examinations were made during the entire course of treatment. This was done for the purpose of ascertaining how he was digesting his food, and also how the liver and kidneys were doing their respective work. It is the only scientific means for finding out whether the work done in the body is good or bad. After the regulation of the diet, and the adoption of sufficient liquid, the urine was gradually changed and a normal condition was established.

Treatment was begun by an effort to gain control of the mental state of the patient, with a view of inspiring courage and hope, and gaining full co-operation. To insure nerve and brain rest, he was directed to take a long rest both before and after meals, and to go to bed early at night and get all the sleep possible. He was advised to drink a pint of hot water an hour and a half before meals and before retiring at night. The object of this was to stimulate secretory and excretory glands, dilute and wash the mucus from his stomach, "flush out" the kidneys, and keep the urine down to a specific gravity of 1.015–18. All starchy and saccharine foods were forbidden, and nothing allowed in the way of nourishment but an animal diet. At first only a few ounces of the muscle-pulp of beef, or beefsteak, were permitted at a meal. The amount was steadily increased, however, until he took twelve ounces or more at each meal. After about six weeks very small quantities of starchy food were allowed, and their effect constantly watched. In such manner he was gradually brought around to a more varied and mixed diet.

The medicines employed consisted of small doses of liquor hydrastia et bismuth before meals, pepsin after meals, and a small piece of rhubarb to insure one free movement of his bowels daily. For his general debility, which was increased at first by the withdrawal of his customary foods, he was given twenty or thirty drops of aromatic spirits of ammonia, or else one tablespoonful of good whiskey in water, three or four times daily.

This line of treatment was persisted in for week after week, his naso-pharyngeal catarrh was duly treated and cured, and he was carefully watched and advised from day to day. As a result, there ensued a prompt disappearance of acidity, flatulence, and distress in his stomach. His nervous system righted up so that he soon began to sleep well, all despondency passed away, and he became hopeful and cheerful. In a few weeks he also began to gain strength and flesh, and a good, fresh color.

Now, after four months, he enjoys good health, has gained nearly ten pounds in weight, is much improved in every way, and, with care in regard to his diet, will keep perfectly well.

Chronic Catarrh of the Bowels.—Mr. W——, aged forty-five, of steady habits and good family history. He spent his early life on a farm, and was healthy and large. Later he engaged in confectionery business and pursued it for a number of years until his health failed. Fifteen years ago he noticed that his general health was declining. Farther along naso-pharyngeal catarrh developed, accompanied by a steadily increasing cough. He then began to seek medical treatment, and went from one physician to another, but obtained no satisfactory help. His whole system seemed involved, and there was doubtless a formidable array of symptoms, for he was informed at one time that his lungs were diseased; again, that his trouble was with the heart and kidneys. This state of affairs went on for seven years. About this time it was discovered that he had a tape-worm, and one was forced away that measured seventy feet. For a while his health remained very poor, but ultimately it improved, and for three years he was better. Then he began to suffer greatly from acidity, flatulency, pain, and so-called inflammation of the stomach. His food did not seem to distress him in a marked degree, but he suffered greatly from distention caused by the gas that accumulatd in his stomach and bowels. He was informed by his physicians that he had "wind dyspepsia." During the last three years he has been severely troubled by gas in his bowels, and by constipation. Every little while, however, he would have attacks of diarrhœa, which was, doubtless, nature's method for relieving the pent-up condition. After he had had several attacks of diarrhœa he made the discovery that the discharges contained a large quantity of what appeared to him to be the coating or lining of the bowels. In other words, he passed thick, tough, stringy, organized catarrhal mucus, which is a common thing in such cases. Besides, the gas and material passed from his bowels were highly offensive, indicating the degree of decomposition and fermentation that was taking place. The gas eructated from his stomach had also the same offensive and disgusting odor. During the years he thus suffered there was a steady decline in strength and flesh; his weight, which had been nearly one hundred and sixty pounds, fell to one hundred and twenty-six pounds, and he became so weak that he could scarcely walk. His family and friends thought that he could live but a short time, and he himself was utterly discouraged. He gave up his business, being too sick to attend to it and not expecting to live. During the long term of years that he was sick he travelled more or less for his health, and had, at different times, the care of ten well-known physicians. These facts are mentioned to convey an idea of the duration, severity, and obstinacy of his condition.

When he came under the following treatment, which he did a year and a half ago, he was thin in flesh and very pale and weak. He complained of despondency, headache, "full-headedness," ringing in his ears, and constant distress in his bowels. His bowels were moving several times daily, and discharging a great amount of gas and thick, tough mucus. At times there would be exfoliations of casts of the bowels, which looked like the lining or mucous surface. Microscopic examination of his blood showed that the red corpuscles were pale, poorly nourished, and shrunken. There were also present a great quantity of mycederma aceti, one of the absorbed products of fermentation. Urinary analysis revealed the presence of considerable biliary matter, and an excess of urates. The urine was dense in appearance, and had a specific gravity of 1.030. Abdominal inspection and percussion discovered general distention from gas, and decided tenderness over the large bowel. This was especially apparent under the constant current of electricity, not alone over motor points, but over the entire bowels.

At the outset of the treatment an effort was made to re-establish a healthy mental state. In the management of such cases it is always of first importance to gain the confidence of the patient, and thus secure cheerful help on his part. He was carefully guarded against physical and mental fatigue, in order to give the bowels rest and save all the nerve-force possible. In addition he was directed to restore a healthy action of the skin by means of stimulating baths, and by friction taken daily. The use of hot water internally was adopted at once, and he began by taking a glassful an hour and a half before meals, and upon going to bed. This amount was steadily increased until he took a pint four times daily. The effect of this was to thin and dissolve the catarrhal secretions, cleanse the stomach, bowels, and kidneys, and help to prevent excessive fermentation. Besides, it increased the volume of liquids in all the tissues of the body, acted as a mild stimulant to all of the emunctories, and thus favored the elimination of morbid material, the natural result of chronic fermentation and deficient oxidation. At times it caused what can be best described as "scourings" or "cleanings," during which the bowels acted more freely,

and discharged large quantities of "sloughed off," stringy mucus. These "clearings" became less frequent, and in time mucus ceased to appear in the stools. The restricted animal diet was also adopted in this case, and consisted at first of small quantities of the muscle-pulp of beef, tender beefsteaks, lean mutton chops, game, and the whites of eggs. He was allowed, farther along, a very small amount of starchy food, with the direction to limit the quantity, or to discontinue it altogether, if it caused gas in his bowels. To offset the sense of extreme debility he felt at times, he was given either twenty drops of aromatic spirits of ammonia, or one tablespoonful of the best whiskey, well diluted, four times daily. As an aid to digestion he was given pepsin, to take after meals. For a nerve-tonic a combination of tincture of cinchona, fluid extract of stillingia, and fluid extract of damiana was prescribed. Later, whenever his liver became sluggish, or his bowels constipated, he was directed to take, at bed-time, a pill composed of a grain and a half of wild cucumber, one-third of a grain of calomel, and one-half a grain of extract of hyoscyamus. The object was to produce one good free movement.

After being on this treatment a few weeks he began to improve, and the symptoms of dyspepsia, fermentation, and diarrhœa steadily disappeared. The discharges from the bowels gradually became natural in consistency and frequency, showing that intestinal digestion was going on normally. Several months later he began to gain flesh, and his weight has now increased to one hundred and fifty pounds. His strength has correspondingly increased, so that he is able to be about all day, attending more or less to business. Discomfort from food is practically unknown, unless he eats too much, especially of starchy foods, thus causing fermentation. By guarding his diet and using hot water he gets along nicely, and is comparatively well. He was under treatment a year and a half. It usually takes from one to three years to cure such cases, much depending upon the severity of the disease.

Remarks.—In perusing the histories given above it has doubtless been noticed that in the management of each case great effort was made to form an accurate diagnosis, and to obtain a thorough understanding of existing conditions. While it is true that subjective symptoms and physical signs were recognized, they were, nevertheless, made secondary to the accurate determinations obtained by repeated study of the blood, the urine, and the fæces. Therefore, in addition to the means ordinarily employed, very frequent microscopic studies of the blood were made; the urine was examined chemically from day to day, and often microscopically; and the character of the fæces inspected as often as seemed necessary. In the treatment of such cases a daily thorough investigation of excretions and products is, in the highest degree, essential. It is the only means of accurately determining to what extent patients are digesting their food, to what degree the liver and kidneys are doing their work, and just what quality of blood is being made. There is no other way for obtaining clear, definite, and reliable results. It must ever be borne in mind that the only way of learning how an organ is doing its work is by frequent and careful study of its products. Morbid organs must inevitably form morbid products. The one is cause, the other is effect. With accurate and comprehensive knowledge thus obtained for a basis, every means of treatment must be subsequently employed that promises aid in effecting a cure. It is a mistake to believe that any one thing, be it food, drink, medicines, rest, or change, will accomplish satisfactory results. There must be, from first to last, the employment of all rational means and methods that tend to remove causes, to restore the healthy action of every organ, to improve the character of the blood, and to build up the nerve-power.

The next step in the management of these cases was the removal of causes that maintained unhealthy action and disease. It would be folly to use space for the purpose of enlarging on the fact that chronic gastric or chronic intestinal catarrh, "twin scourges of humanity," is invariably caused and perpetuated by something or some condition that is constantly acting. In the great majority of instances this something is unhealthy and improperly digested foods. As a rule, these foods are undergoing morbid changes in either the stomach or bowels, or in both, and perpetuating and augmenting disease. A process is in constant operation that is not only keeping up irritation and excessive secretion of mucus, but also generating abnormal elements which take the form of "gases," "ferments," "ptomaines," or "alkaloids." These are absorbed into the blood, carried into every part of the system, and work their deleterious effects upon organs, muscles, and nerves. Hence comes the primary importance of dispensing with every food that does not digest properly. As is well known, the foods most liable to undergo fermentation and cause gastro-intestinal catarrh are those of a starchy and saccharine nature, as, for instance, bread, oat and corn meal, rice, pastries, potatoes, beans, and, in short, most of the vegetables. These are the foods that, in many persons, cause acidity, fermentation, and irritation, and thus keep the alimentary tract more or less filled with abnormal fluids and gases. All foods of this class were looked upon as causes in the foregoing instances, and were therefore more or less rigidly excluded from the diet for days and weeks, and even months. Inasmuch as prompt relief followed their exclusion, it is reasonable to believe that they had been the cause of the miserable effects that had long prevailed. The complete exclusion of starchy and fermentable foods is an interesting feature, owing to the fact that such exclusion is completely contrary to the usual methods of treating such cases, starchy foods being generally relied upon and an animal diet excluded. Indeed, nearly all authorities have claimed that persons having gastro-intestinal catarrh should be dieted on starchy and saccharine foods, and omit animal food entirely. In such manner they have been dieted on the very articles and elements that are the chief causes of fermentation, and the disease perpetuated instead of cured. It needs no argument to prove the absurdity of trying to cure chronic fermentation with fermentable foods. It needs no logic to explode the sheer nonsense of feeding patients on oat meal, then washing it out of the stomach in a few hours, sour and undigested, and then feeding the patient again with the same material. This is being done in New York at the present time. On the other hand, the patients referred to were persistently guarded against starchy foods, were fed for a long time exclusively on animal foods, which are non-fermentable, and were promptly relieved and eventually cured. It was not the desire to place these patients arbitrarily on a particular diet, but rather on one that they could digest and assimilate. Thus far, after several years of trial in my practice, an animal diet has been found to yield incomparably better results than any other, and for this reason it was employed. It was, of course, essential to ascertain from time to time if it was being properly digested, and this was done by a careful study of the blood, the urine, the fæces, and all other symptoms, according to the methods already mentioned. It would be impossible to state too strongly the importance of frequent and thorough study of the above-named products, and of all relevant symptoms connected with the case. The fact that these patients, and hundreds more who have been similarly dieted, were eventually cured, tends to demonstrate that an animal diet is the most easily digested, and that it contains all the potential elements needed to meet the demands of the system. The great thing is to have the stomach and bowels thoroughly cleansed by copious quantities of hot water, and then to allow the patient only as much animal food as can be digested. When used thus it agrees with nearly all cases, enables the organs to regain their power, improves the quality of the blood, and restores the tissues of the entire system.

Another essential feature in the treatment of the cases alluded to was the long-continued internal use of hot

water. As stated before, it was given for the purpose of supplying to the system a sufficient quantity of liquid, stimulating the secretory and excretory glands, diluting and washing out the excessive catarrhal mucus collected along the intestinal tract. It is simply impossible to cure catarrhal diseases of the stomach and bowels so long as their surfaces are covered with tough mucus, yeast-germs, and excremental filth. These decomposed and deleterious products must first be washed out, and then kept washed out, by a free and methodical use of hot water. This methodical use must be regulated by the intelligence and judgment of a physician who has a definite purpose in view and knows how to accomplish his purpose. In the treatment of these cases it is necessary to continue its use for a long time. It requires months, and in some instances even two or three years, to cleanse the digestive tract and the blood of their morbid contents. It is, indeed, not saying too much in claiming that the free use of hot water is an inseparable and invaluable adjunct to this radical method of curing chronic diseases.

In regard to the use of medicines but little need be said. Those employed were simple and of well-known character, and were used to meet urgent indications. On them but little reliance was placed, farther than to meet certain temporary needs. In short, they were used only so far as they promoted the appetite, aided the digestion, augmented the tone of the nervous system, and stimulated or checked secretions. In catarrh of the stomach and duodenum specific medicines sometimes do direct good, but below these points their effects are practically *nil*. But it is safe to say that no single means or medicine can effect the cure of these long-standing and desperate conditions. There must be not only rational exclusion of *every well-known element of causation*, but also the adoption of *all measures* calculated to restore function, and build up the blood and the general system.

In conclusion, the results obtained in the instances cited, and in scores of cases besides, tend to establish three important facts:

1. That the majority of cases of gastro-intestinal catarrh that "go the rounds" in vain and become the bane of medical practice, are entirely curable.

2. That prolonged use of from one to two quarts of hot water daily is in no sense injurious, but, despite all conflicting statements to the contrary, is, when given with precaution for a definite purpose, and according to well-established scientific guides, one of the most grateful and useful remedial means that can be employed.

3. That an animal diet, properly selected and prepared, is the best tolerated, the most easily digested, and the most promptly absorbed of any diet thus far known. When the rules and methods above stated have been observed, it can be used for months and years without occasioning the slightest harm. In no sense does it tend to cause gout, rheumatism, or Bright's disease, as is sometimes ignorantly claimed. In connection with the diseases above described, its great utility is to tide the patients over until they can live well and comfortably on a diet composed of two-thirds animal and one-third starchy food, which is the normal proportion.

THE "BELLY BAND" FOR THE NEW-BORN.—Dr. Ady (*Pacific Medical and Surgical Journal*) believes that the "belly band," however made, is a relic of barbarism—uncomfortable and mischievous, often causing and never preventing hernia. The inguinal region is the weakest part of the abdomen. Instead of protecting this the band, on the contrary, forces the intestines down into it. Even if the umbilical opening has not properly closed, the pressure of the band about the circumference of the body will only crowd a knuckle of intestine into the aperture and effectually keep it open, instead of allowing it to close, which it will generally do if left to itself. He would, therefore, advise that all bands, skirts, etc., that punish the baby be left off.

Clinical Department.

SUPRAPUBIC CYSTOTOMY IN A CASE OF OBSTRUCTIVE SENILE HYPERTROPHY OF THE PROSTATE GLAND.

BY G. T. RICHARDSON, M.D.,

CHARLESTOWN, W. VA.

ACCORDING to Reginald Harrison, hypertrophy or enlargement of the prostate gland is a condition which affects one-third of the male population [of the world?] who have passed the age of fifty-five years. And if it be true that there are "no known means of preventing it," the announcement may be accepted with complacency by the other two-thirds, but will be looked upon as a rather lugubrious greeting to the coming man. However this may be, there are few medical men, I imagine, even among the non-specialists, of any considerable experience, who have not encountered this enemy of the aged strongly entrenched. The following case presented some features which have not come under my observation before:

G. E——, seventy years of age, suffered with irritability of the bladder during the latter part of the summer of 1888. His condition grew steadily worse under a self-instituted treatment with patent medicines, and in October reached the culmination of a well-established cystitis. He had not up to this time made formal application to me for treatment, and when I proposed to examine his prostate, and hinted at surgical interference, he decided to try the "Safe Cure" a while longer.

Finally, at four o'clock A.M. on December 25, 1888, after weeks of great suffering, which had well-nigh exhausted his power of further endurance, he was seized with a fit of retention, and sent for me.

Before proceeding to catheterize I made a careful examination of the prostate, which I found considerably enlarged, but not greatly so, at least not in the direction of the rectum, and I could not make out any inequality in the lateral lobes. In attempting to introduce the catheter—an ordinary silver one, No. 11, American scale—I encountered a stricture in the membranous portion of the urethra, which was passed after a while, but the obstacle beyond was utterly impassable. I called a consultant, and we both tried with a series of smaller instruments, but failed to enter the bladder.

The distention was now very considerable, and the suffering of the patient extremely great; so without further delay I aspirated above the pubes, taking about a quart of water. This brought relief and sleep—brief indeed, but still the first he had enjoyed for many hours. Returning before the bladder had become again distended, I made another attempt to introduce a catheter, but with no better success than before. So I now determined to desist from these worse than useless efforts to enter the bladder through the urethra, and to rely upon the aspirator instead. Accordingly, about five hours after the first aspiration a second was performed, and then a third, and so on for two or three days, and yet there was no improvement. I proposed cystotomy, but he strenuously opposed the operation, and was ably seconded by his wife, and the aspirating went on, with a rapid lessening of the interval between times, and a fearful increase in the vesicular irritability and tenesmus, due no doubt in part to these numerous punctures, until at last, seeing that my patient was surely failing, and believing that to pursue such a course any longer would amount to gross malpractice on my part, I refused to aspirate another time; and, with the tardy acquiescence of the patient and his wife, I performed the operation of suprapubic cystotomy after the plan recommended by Dr. Hunter McGuire (see *Virginia Medical Monthly* for October, 1888).

The drainage-tube introduced after the operation produced so much irritation that I removed it in about two hours, and never used it again.

The wound and parts around were kept clean by frequent spongings with carbolized warm water; and after each sponging the wound was covered with a small piece of absorbent cotton saturated with mercuric chloride solution 1–1,000, and over this a larger pad. This completed the dressing.

Everything went on well until the third day (January 10th) when the temperature rose to 103°, and there was marked tenderness and redness on the right side of the abdomen, extending from the wound upward and outward about five inches.

The patient had lain on his right side a good deal, thus favoring the filtration of urine into the tissues, and this was no doubt the cause of the trouble. But it soon passed off under a change of position and the application of a stronger solution of carbolic acid. On the eighth day after the operation the sutures were removed. On the fifteenth the urine passed naturally through the urethra, with only a little spirt through the fistula at the beginning of micturition. On the eighteenth day the patient was up and walking about the house, and, though weak from the severe ordeal through which he had passed, declared he had not felt so well for six months, and the opening in the bladder was nearly closed. I had intended to keep it open for some time longer as a safety-valve, but every unpleasant symptom having subsided, and the patient expressing great anxiety to be relieved of the inconvenience of having a "hole in his belly," I did not insist upon it. I saw him last on the first of February. The wound had been completely closed for several days. He could retain his urine three or four hours without discomfort and pass it without trouble, and there has been no unfavorable result thus far.

The space penetrated by the aspirating needle covered a surface area about the size of a silver quarter.

In operating this space was bisected, revealing a congested and blackened condition of the tissues down to the bladder itself. And this condition no doubt favored the cellulitis set up on the third day. For this reason so many punctures ought not to have been made. The cystotomy should have been done earlier. But in private practice the surgeon is no autocrat, and is often hampered and thwarted by the whims or ignorance of his patient. So in this instance relief was refused except by means of the aspirator. Now it was practically impossible to introduce the cannula through the same track each time, and I found the plan of leaving it in the bladder gave rise to the danger of still further and more seriously wounding the mucous coat of the collapsed viscus by the sharp point of the instrument.

The aspirator is indeed a boon in retention when catheterization is impracticable; but the relief it gives is only temporary, and it must be regarded as a poor substitute for free drainage in all cases in which residual urine is a factor. It will be observed that the catheter was not brought into requisition after the first three or four ineffectual attempts to introduce it. And so without any irrigation of the bladder—save by the overflow and free escape of the healthy urine itself—without any prostatotomy, without any catheterization, the bladder and the prostate and the urethra, after a complete rest of less than thirty days, have regained a nearly healthy condition. If further trial establishes the fact that suprapubic cystotomy can be relied on to accomplish such results it will have a brilliant future.

SUICIDE IN FRANCE.—The total number of suicides in France during the year 1887 was 7,572, of which 2,168 are attributed to mental afflictions of different kinds, 1,228 to physical suffering, 975 to domestic troubles, 800 to drunkenness, 483 to poverty, 305 to pecuniary difficulties, 208 to the desire to avoid imprisonment, 100 to the loss of employment, 89 to the fear of exposure, 56 to the loss of relatives, and 25 to the dread of military service. Among the other causes specified in the returns, 227 suicides are put down to jealousy and crossing in love.

A MEDICO-LEGAL CASE, IN WHICH THE NEEDLE OF AN ASPIRATOR WAS PLUNGED PAST THE RIGHT PLEURAL CAVITY, THROUGH THE DIAPHRAGM, AND INTO THE LIVER, WITH FATAL EFFECT.

BY J. M. BALL, JR., M.D.,

WATERLOO, IOWA.

CASES of alleged malpractice, in which an aspirator is the instrument producing death, are extremely rare; so rare, in fact, that after a prolonged search the writer has been unable to find a single recorded instance. A case which merits the title of this paper has just been tried a second time in the district court, convened in this city, and has attracted great attention in local medical circles. The first trial was had in February, 1886, and in each instance a verdict was returned in favor of the plaintiff. The present paper is written with an honest desire to benefit the profession, and to sound a note of warning in regard to an operation which so many of the faculty are called upon to perform, and in which the possibility of producing harm seems rarely to have entered the operator's mind. The petition of plaintiff sets forth that the defendant is a practising physician in Waterloo, Iowa; that said A—— R——, in April, 1885, being in feeble health by reason of malarial poisoning, employed the defendant in his professional capacity; and that the defendant accepted such employment, thereby tacitly agreeing to bring to the treatment and relief of the deceased a reasonable amount of professional skill.

The plaintiff further alleges that the defendant made an incorrect diagnosis of the case; and decided "that it was necessary and requisite to the treatment of said R—— that a certain surgical instrument known as an aspirator should be inserted into the body of said R——. And plaintiff alleges that the use of said instrument was unnecessary and without reasonable excuse. That, therefore, and in pursuance with his determination, the defendant proceeded and did insert into the body of the said R—— the instrument aforesaid. That said instrument was by the defendant ignorantly, unskilfully, carelessly, and negligently inserted and used; the liver, diaphragm, and peritoneum of said R—— thereby wounded and cut; great pain and suffering inflicted upon said R——; and that therefrom said R—— did thereafter, and on or about April 28th, 1885, die." Damages were asked in the sum of five thousand dollars.

In his answer to the petition of the plaintiff, the defendant "denies that the use of the aspirator by himself, in making a diagnosis of the disease of which the said R—— was ill, was wrongful, or without warrant or excuse therefor.

"That, as to whether said instrument caused great pain and suffering of the said R——; as to whether the liver, diaphragm, and peritoneum were punctured or cut by said aspirator, the defendant has not sufficient information to form a belief as to the truth thereof, and asks that such allegations be taken as denied."

The undisputed testimony shows that A—— R——, a farmer by occupation, and thirty-eight years of age, was a strong, robust, and healthy man on December 24, 1884, at which time he started on a journey to visit friends in New York; that he was absent about ten weeks, and that while absent he contracted a severe cold which settled on his lungs. In March, 1885, he consulted a physician, who told him that he was suffering from malarial poisoning. Dr. —— was first called to attend the deceased on April 20, 1885. He found marked dulness over the right side of the chest, extending downward from a line drawn horizontally across the right side, and about one inch above the nipple. The doctor expressed the opinion that his patient was suffering from pleurisy. Some remedies were prescribed, and the defendant returned home. This was on Monday. On the following Thursday the doctor returned with an aspirator, and proposed to aspirate the right pleural cavity for diagnostic purposes.

This was consented to by the patient. The doctor did not have counsel, and the persons who assisted in the operation were laymen. The aspirator was used, but no fluid was found. Immediately thereafter his breathing became rapid and difficult, and great pain, which was paroxysmal and frequently recurring, was complained of in the right hypochondriac region. In twenty-four hours he was delirious, and his abdomen tympanitic and swollen. At 4. A.M. of the following Tuesday the patient died. The needle of the aspirator used was found on measurement to be one millimetre in width, and three and one-eighth inches in length, from the eye to the shoulder.

The post-mortem examination showed that the thoracic organs were normal, except the lower lobe of the right lung, which was the seat of hepatization. The abdomen was tympanitic, and showed evidences of diffuse general peritonitis. The superior surface of the right lobe of the liver presented a wound about one and one-eighth inch in length, and varying from one-eighth to three-sixteenths of an inch in depth. Between the superior surface of the liver and the under surface of the diaphragm, and adherent by plastic exudation to the latter, were several flattened clots of blood each about the size of a half-dollar. The diaphragm, at a point corresponding to the wound in the liver, presented evidence of an intense inflammation.

The conflicting testimony is in regard (1) to the seat of puncture of the chest-wall, and (2) to the depth to which the needle was introduced.

1. The defendant swore that he inserted the needle at the sixth intercostal space, on the right axillary line. A gentleman present swore that "the puncture was about two inches below and a little to the right of the right nipple."

2. The defendant stated under oath that he first introduced the needle about an inch, and then turned the stop-cock of the aspirator; then, obtaining no fluid, he pushed the needle about half an inch further with a similar result. The testimony of the spectators leaves it doubtful as to the depth to which the needle was inserted.

Verdict.—At the first trial the Court instructed the jury that, inasmuch as the plaintiff had introduced no testimony to show the value of the deceased's life, damages, if found at all, could be merely nominal, such as six cents or one dollar. Jury found for plaintiff in the sum of one dollar. Verdict was set aside by the Court as unwarranted by the evidence. At the second trial the jury found for the plaintiff in the sum of fifty dollars.

Remarks.—The operation of thoracentesis is of great antiquity, being mentioned in the writings of Hippocrates, Galen, Paulus Æginetæ, and Celsus. It was performed by them for the relief of empyema, but the operation, as applied to cases of hydrothorax was not performed previous to the first part of the seventeenth century.

Among the important questions bearing upon the preceding case, and on which the experts were requested to enlighten the jury, are the following. They are appended for the benefit of the reader, and may furnish food for thought.

I. "Do you know of any cases on record in the medical text-books where the surgeon, in attempting to remove an effusion from the pleural cavity, has plunged his instrument through the diaphragm, into the liver, with fatal effect?"

Answer. Donaldson, in "American System of Medicine," vol. iii., p. 533: "Aran plunged a trocar into the liver when operating through the same point," viz., the seventh intercostal space. Aitken, "Science and Practice of Medicine," vol. ii., pp. 673 and 674, edition of 1866, says: "The most appropriate spot for puncture is between the seventh and eighth, or eighth and ninth, or ninth and tenth ribs, in a line let fall from the lower angle of the scapula; but as a rule, let the trocar be introduced as low down as possible, consistent with the safety of important organs in the chest or abdomen. *The exact position of the liver and spleen must be determined first in every instance* (italics mine). Laënnec himself once transfixed the diaphragm and pierced the liver, and that through the *fifth* intercostal space. An enlarged liver or spleen may be detected as high as the fifth rib. Dr. Watson once witnessed an operation, in which the trocar was pushed through the diaphragm into the spleen, which was unusually large. The patient died a day or two later of peritonitis." . . . "The point of the instrument should be raised rather than depressed, so as to avoid injury to the diaphragm, liver, or spleen."

II. "Supposing a needle three inches long be inserted into the sixth intercostal space, over the right side and on the axillary line, and at a right angle to the chest-wall, what important organs would such a needle pass through or injure, assuming the parts to be in their normal position?"

III. "Would it be possible in your opinion to produce a wound, one inch in length and one-eighth of an inch deep, by means of the needle of an aspirator introduced at right angles to the body, for a distance of three inches, into the seventh intercostal space on the right side, assuming the organs to be in their normal position?"

IV. "What is the distance from the sixth intercostal space on the mid-axillary line of the right side to the nearest point of the liver, assuming the parts to be in their normal position?"

V. "Assuming the needle of an aspirator to be inserted at the sixth intercostal space of the right side, passing through both layers of the pleura, through the diaphragm, and through both layers of the peritoneum, would it be possible to produce, in the convex surface of the liver, a wound one inch in length and one eighth of an inch in depth?"

A PECULIAR CASE OF DETACHMENT OF THE RETINA.

By F. E. D'OENCH, M.D.,

NEW YORK.

The following case of detachment of the retina possesses some points of interest which seem to render it worthy of being put on record:

Michael B——, aged forty-five, came to the German Dispensary with the complaint that the sight of his right eye had rapidly failed during the last two weeks. That of the left had been poor for more than two years. An examination of the right eye revealed an extensive detachment of the retina, involving the outer portion and extending beyond the macula lutea toward the optic nerve, the fovea centralis appearing as a dark-red spot in the detached retina. The peculiar feature of this case, however, was found in the presence of numerous small, white dots scattered throughout the detached portion, but most numerous near the periphery, apparently of the size of a pinhead or less in the ophthalmoscopic image, and not confluent. The whole presented a picture like that of an astronomical chart, in which the stars are represented by dots of varying magnitude. The patient had perception of light in the detached portion, the detachment, as already mentioned, being a very recent one. The tension was normal. Cases of this kind have been observed before, but they are of rare occurrence. Leber[1] mentions them, together with other peculiar changes, but does not give any explanation of their formation. Other references to them I have not been able to find.

In the absence of any histological examination of such an eye we can only conjecture as to the nature of these dots; it is probable, however, that they are the result of some acute degenerative process. In conclusion I might add that neither albumen nor sugar was found in the urine.

Dying Song to Electricity by Criminal.—"I'm Going 'Ohm to Dynamo."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 9, 1889.

PASTEURISM AND THE PALACE OF HYDROPHOBIA.

THE extraordinary *éclat* attending the recent opening of the Pasteur Institute in Paris has been duly chronicled by the press, both secular and medical. It is certainly a pleasing reflection that so much money could have been raised for purely scientific purposes. The study of bacteriology will doubtless receive a further strong and healthy impetus from the erection of the vast and perfectly equipped laboratories connected with this biological institute. The French government alone has allotted the sum of $25,000 a year to defray the current expenses of this magnificent workshop of experimental research.

But, as regards the more specific purpose of this Institute, namely, the practice of Pasteur's anti-rabic inoculations, the question seems an allowable one: "Is the game worth the candle?" On this score even France has its doubters, although everyone knows that the Frenchman is much given to exuberant self-praise in all that pertains to "*la gloire de la patrie.*"

In a recent issue of the *Journal de Médecine de Paris*, the editor, M. Lutaud, boldly attacks the very essence of Pasteurism in relation to the prevention of rabies. It may not be generally known to our readers that Dr. Lutaud is the arch-enemy of the Pasteur system, having indeed written an entire volume in denunciation of the practice. It seems but fair to make this statement, as there are always two sides to every controversy. The journal cited above has remained silent for many months, and it appears that this has been construed by M. Grancher, the chief assistant of Pasteur, as an admission of defeat. It is in order to refute any such notion that the editor has now returned to this subject.

There is one glaring fallacy in likening anti-rabic inoculation to vaccination for the prevention of small-pox. It is this: Vaccination is practised before the invasion of the system by the virus of small-pox. But in hydrophobia a poison is introduced into a body already supposed to be infected with a similar virus.
